The middle ear is an air-filled space and is located behind the tympanic membrane which contains the bones of hearing (ossicles) called malleus, incus, and stapes (Munir and Clarke 2013). These ossicles constitute the ossicular chain which help with the transmission of sound to the tympanic membrane and then to the inner ear (Seikel et al. 2010). Another part of the middle ear is the Eustachian tube which occupies the air space between the nose and the throat (Balkany and Brown 2017).

In the middle ear there are two tympanic muscles that are connected to the ossicles. These are called the stapedius and the tensor tympani. The function of the stapedius is to rotate posteriorly the footplate of the stapes stiffening the ossicular chain. The function of the tensor tympani is to pull the malleus anteromedially, thus reducing

the movement of the tympanic membrane. These two muscles stiffen the transmission system of the middle ear, monitoring the acoustic signal in the lower frequencies, thus protecting the ear from high intensity sounds (Seikel et al. 2010).

An additional part of the middle ear is the Eustachian tube, which forms a link between the nasopharynx and the middle ear. The cranial nerve VII passes runs through this pathway (Munir and Clarke 2013). The function of the eustachian tube is to allow mucous flow away and oxygen run through and out of the tube. It, also, works as a way to equalize the pressure levels in situations where pressure is changed such as under the water or in high altitudes (Balkany and Brown 2017).

Reichert's (1837) hypothesis on comparative morphology has contributed to the evolutionary understanding of the middle ear's ossicles, the malleus, and incus. According to his study, these ossicles were derived from the cartilages of the upper and lower jaw elements of the articular and quadrate amniotes. Further evidence was found to support this hypothesis based on fossil records in South Africa and Russia (Takechi and Shigeru 2010).

Furthermore, Manley (2010) has noted that the tympanic middle ears were developed independently and that their origin is unique. He further explained that evolution takes place independently in similar groups, and that the results developed from the same structures could be similar. He also mentioned of the possibility of a random evolution and that the developments of the middle and inner ear were essential for hearing in high frequencies. With the enlargement of the brain, the tympanic middle ear in therian mammals was developed, subsequently creating a secondary palate that helped with the development of a pressure system in the middle ear (Manley 2010).

The Inner Ear

The inner ear is sectioned into the cochlea and the balance system (the vestibular system). The first representation of the human and mammalian cochlea was discovered in 1561 (von Bekesy 1948) and the phenomenon of resonance was

proposed by Duverney in 1683 (Mudry 2000) who based his observation on the resonance of two piano strings in tune with each other. The careful drawings of Magnus Gustaf Retzius (Jelliffe 1920) who depicted the cytoarchitecture of the organ of Corti has given an elaborate description of the membranous labyrinth, cross sections of the cochlea, and the surface of the organ of Corti based on different stages of development (Johnsson and Hawkins 1967).

The balance system, otherwise called vestibular system, is made up of a vestibule, located between the cochlea and the semicircular canals. A structure called the osseous labyrinth (or bony labyrinth) is consisted of the cochlea, the vestibule, and the semicircular canals. The membranous labyrinth lies in the osseous labyrinth; it can be described as a sac filled with fluid (Boulpaep and Boron 2005). Both the bony and the membranous labyrinth are complex balance organs of the inner ear (Hain and Helminsky 2007).

Cochlea

The cochlea has a snail shape and has compartments filled with fluid. These compartments are in a form of a spiral and contain the organ of Corti, which is the receptor for acoustic information (Chang and Khana 2013). The organ of Corti and the vestibular organ are enclosed in the temporal bone (Moller 2013). There are more than 15000 hair cells in each cochlea which yield electrical signals based on the vibrations of the inner ear fluid; consequently, these electrical signals are perceived by the brain as hearing (Balkany and Brown 2017).

The cochlea distinguishes the sounds based on their frequency in order different sounds activate different auditory nerve fibers. This takes place in the inner hair cells. The outer hair cells help to reduce the friction on the basilar membrane and increase its vibration breadth. They also increase frequency selectivity, according to the intensity of sound, and frequency selectivity is decreased when the intensity of sound is increased, which causes the cochlea to function in a nonlinear way in order to compress the sound before the innervation of the auditory nerve. This process helps to

distinguish the sounds in the auditory nerve based on their intensities (Moller 2013).

The organ of Corti, as a part of the cochlea, is composed of a specialized structure consisted of hair cells, and is located on the basilar membrane. In essence, this structure organizes the auditory transduction (Pickles 2012, pp. 28–33). It is covered with a gelatinous and fibrous fold called the tectorial membrane, consisted of molecules and collagens known as tectorins, which play a significant role for the hearing process (Pickles 2012, pp. 28–33; Richardson et al. 2011). The organ of Corti generates sharply tuned traveling waves by the process called mechanotransduction based on electrochemical reactions in the cochlear scalae (Pickles 2012).

Otolith

Otoliths are describes as tiny carbonate particles that compose the otolithic membrane. The otolithic membrane accommodates the utricle and the saccule inside the vestibule (Chang and Khana 2013; Seikel et al. 2010). It, also, covers the utricular macula which is a sensory organ consisted of hair cells and cilia. The saccule is located near the scala vestibuli in the vestibule and is consisted with macula and the otolithic membrane. The linear motion or the tilting of the head creates a movement force between the otolithic membrane and the macular surface, which result in the bending of the hair cells (Oghalai and Brownell 2012).

Conclusion

The main structures of the peripheral auditory system were discussed, namely, the outer ear, middle ear, and inner ear, along with the structures of the cochlea and the otoliths.

Definitions

Aunts, paternity Uncertainty, Kin caregiving, Matrilateral, Patrilateral, Asymmetric kin investment

Introduction

Despite being forgotten in research, maternal and paternal aunts are highly invested and play an essential role of an “adjunct mother,” thereby providing childcare, guidance, support, and affection to their nieces and nephews (Milardo 2009, p. xvi). The aunt-child relationship can be consanguineous or formed through marriage and therefore includes the sisters of a father (paternal aunts) or mother (maternal aunts) or the wives of father’s brothers (paternal aunts) or mother’s brothers (maternal aunts).

One of the most decisive factors in the degree of investment in nieces and nephews is a sense of solidarity or the relationship between parents and their siblings’ family, which can be further

influenced by contextual factors listed here. For instance, higher “associational (frequency of contact between parents), consensual (the similarity of attitudes and emotions between parents), functional (perception of support), normative (sense of obligation) and a structural (residential proximity) solidarity” (Milardo 2009; p. 12) can remarkably moderate ideas of kin-keeping and investment in nieces and nephews.

Laterality and Gender Effects

Notably, the scholarly examination of above listed contextual factors brings into light the concept of asymmetric kin investment or the laterality effect. Studies in favor of laterality effect suggest the occurrence of higher investment in nieces and nephews by a maternal aunt than a paternal aunt. To elaborate, in matrilineal societies, blood-related maternal aunts perceive a stronger sense of genetic relatedness and emotional closeness in comparison to paternal aunts. These perceptions are further influenced by paternity uncertainty, opportunities for frequent contact, stronger relationships between sisters, and young female’s (in this case maternal aunt’s) interest in learning maternal behaviors (Salmon 1999; Parent et al. 2013). Additionally, Tanskanen (2015), in the Finnish sample, showed that childless aunts are more likely to invest in their nieces and nephews, perhaps because they have more time and resources.

On the contrary, studies from patrilineal societies conclude otherwise. Patrilineal societies mandate higher associational, structural, and normative solidarity to the husband’s family to ensure higher perceptions of genetic relatedness and a lower uncertainty of paternity. Consequently, patrilineal societies have more significant investment by paternal aunts than maternal aunts (Pashos 2000; Milardo 2009; Euler and Weitzel 1996).

Despite cultural variations on the laterality effect, aunts being females and therefore normed kin-keepers undoubtedly provide more intense and frequent caregiving to their nieces and nephews than uncles. To further

investigate, Gaulin et al. (1997) compared their US sample with Euler and Weitzel (1996). The authors reported that in the US sample, aunts invested more regardless of whether they are paternal or maternal. Therefore, unlike Euler and Weitzel (1996) study of German families, laterality played a smaller role than gender in the US sample.

Impact of Aunt Care on Development in Minority Families

After grandparents, aunts contribute the most in all domains of development. Aunts can be a role model, teacher, friend, or an allomother and provide meaningful family connections that can have a lasting and valuable effect on the development trajectory during adversity (Ellingson and Sotirin 2006) to strengthen families (Davis-Sowers 2012).

As noted, these positive effects are particularly relevant and distinct in minority families. Parent et al. (2013) found that among African American families in the USA, the warm relationship between maternal aunt and their nieces and nephews was negatively associated with internalizing and externalizing behaviors. Cross-cultural comparison studies in the USA and Finland reproduced similar results. Erola et al. (2018) found that resources at an extended family level, particularly of uncles and aunts, are positively associated with socioeconomic attainment among nieces and nephews. Likewise, Allen et al. (2008) concluded that among Latino families, extended family members such as aunts are untapped resources that bridge the intergenerational gap between parents and adolescents.

Aunt Care and Aunts

Davis-Sowers (2012) examined the determinants of the aunts’ decision to care for their nieces and nephews in Black families. He found that aunts have little to no authority in denying/accepting care. The participants reported that decisions to parent are deeply rooted in gendered norms,

sense of obligation to the family, an occurrence of crisis-like situation, and religious values that promote kin-keeping. Despite the lack of agency, aunts were inclined to caregiving as it offers opportunities to build a personal identity, a higher sense of self-efficacy, and satisfaction of making a difference in the lives of their family.

The above article Davis-Sowers (2012) alludes to feminist criticisms of gendered caregiving. Strong-Boag (2009) agrees that after grandparents, aunts are first in line to provide care. Nevertheless, this reliance at the time crisis contributes to unpaid emotional and physical labor for women and undue pressure of being responsible for children's future.

Conclusion

Currently, we have a handful of research that solely pertains to the impact of aunt care on lifespan development. In extended family care literature, aunts are lumped together with grandparents and uncles, and therefore examining their role is challenging. The research supports the positive and vital role of aunts on individual development. Since many aunts are expending time, energy, and effort in maintaining or supporting relationships with their nieces and nephews, scholarly examination of their role is warranted.

Aurelio José Figueredo

Tomás Cabeza de Baca
Health Psychology, University of California, San Francisco, San Francisco, CA, USA

Definition

Aurelio José Figueredo is an evolutionary personality psychologist who has made significant contributions to research on sexual violence, environmental harshness and unpredictability, and on psychometric approaches toward measuring human life history.

Aurelio José Figueredo is an Evolutionary Personality Psychologist from the University of

Arizona in Tucson, who serves in the Departments of Psychology and Family Studies and Human Development. In addition to his full professor appointments, Professor Figueredo directs the Ethology and Evolutionary Psychology (EEP) graduate program. His most notable contribution to the field of evolutionary psychology was to more fully develop the *psychometric approach* to the assessment of human life history strategy by discovering the *K-Factor*, a latent higher-order construct of psychological, behavioral, and cognitive traits that are theorized to comprise a cohesive and comprehensive life history strategy. Since its inception in the early 2000s, the psychometric approach has generated much derivative research as well as controversy (see Copping et al. 2014). The sections below briefly discuss Professor Figueredo's private life, education, and a selection of his contributions to the field of evolutionary psychology.

Private Life

Aurelio José ("AJ") Figueredo was born in Victoria de las Tunas, Oriente, Cuba, on 27 December 1955 to Yolanda Fulgencia Rodríguez and Alfredo Odón Figueredo. He had two older siblings at the time, Alfredo Ezequiel Figueredo and Yolanda Inocencia Figueredo. Most notably, AJ's older brother became an Anthropologist who eventually achieved the status of world expert in Caribbean Archaeology and Territorial Archeologist for the US Virgin Islands. When he was only 3 years old, AJ's parents had to flee their native country under threat of execution by the newly established communist dictatorship of Fidel Castro; 9 months later, AJ and his two older siblings emigrated to the USA to join their parents, escorted by their grandmother María del Pilar Lalana de Figueredo. His younger sister, Ana María Figueredo, was later born in Brooklyn, New York, and is the only original immediate family member besides AJ remaining alive at the time of writing. AJ has been married since 1983 to Maureen Jacobs Figueredo, and she gave birth to one daughter, Alyssa Mia Figueredo, in 1987.

Academic Education

Having spent most of his childhood on the east coast, AJ moved west and earned a bachelor's degree in Psychology at California State University, Los Angeles, in 1983. AJ was then accepted into the University of California, Riverside, earning his master's degree in 1985 and receiving his doctorate degree in 1987, specializing in comparative psychology, physiological psychology, and quantitative psychology. His graduate advisor was Lewis Petrinovich, a comparative psychologist who worked extensively on song learning in the white-crowned sparrow and, later in life, wrote several books on the evolution of human moral intuitions.

The breadth of AJ's early training involved ethological and comparative research mainly focusing on biologically prepared behavioral development in insects, specifically focusing on conditioned host selection in the parasitoid jewel wasp, as a function of changing ecological conditions during development (Figueredo 1987, 1989). He additionally extended his comparative work to include the conditioned response to sex pheromones in the oriental fruit moth (Figueredo and Baker 1992), the quantitative ethology of song learning in the zebra finch (Figueredo et al. 1992), and the latent structure of personality dimensions in both stump-tailed macaque and the zebra finch (Figueredo et al. 1995) as well as in the common chimpanzee (King and Figueredo 1997).

Major Contributions to Evolutionary Psychology

The Evolutionary Psychology of Sexual Violence. Professor Figueredo's early work focused on the cross-cultural examination of aggressive behavior, especially sex offending, intimate partner abuse, and family violence as well as sexually motivated interpersonal aggression in general. This body of cross-cultural research asserted that issues that precipitated intimate partner violence were primarily fueled by sexual conflict between men and women. Men in these situations sought to control and retain sexual access to women by

coercive and aggressive means (Figueredo and McCloskey 1993). Further, the men often engaging in these coercive strategies were found to be low in mate value (*Competitively Disadvantaged Male Theory*; Figueredo and McCloskey 1993) and to have fast life history strategies (Figueredo et al. 2012; Gladden et al. 2008). Another finding from this body of research is that aggressive individuals are abusive and conflictual across different social domains (Figueredo et al. 2012), including the abuse of women and children (Figueredo and McCloskey 1993; Gladden et al. 2013; McCloskey et al. 1995).

The Hierarchical Latent Structure of Human Life History Strategy (the K-Factor). Briefly, life history theory posits that organisms are given a finite amount of bioenergetic resources that they must allocate across varying facets of development. These trade-off decisions are influenced by the local conditions of the environment in which the organism resides, with resource allocation occurring in developmental domains that best maximizes resources for survival and reproduction (see Life history theory or Fundamental Strategies, encyclopedia entries). Life history strategies reside on a continuum, whereby fast life history strategies are oriented toward short-term mating and low parental care, while slow life history strategies are oriented toward long-term mating and high parental care. While Professor Figueredo has contributed to many aspects of human life history theory, one of his most notable contributions to the study of human life history was to put forth and test the hierarchical latent structure of the *K-Factor*, a psychometric extension of Rushton's (1985) psychosocial life history model (see Figueredo et al. 2013 for a summary). Both models posit that life history strategies encompass a coordinated suite of traits and characteristics that range from reproductive history (e.g., age of puberty, number of births, etc.) to behavioral, cognitive, and personality traits. One of the most comprehensive measures of life history strategies (*K*) was developed by Professor Figueredo and his colleagues called the *Arizona Life History Battery* (ALHB; Figueredo 2007) and the short-form version called the *Mini-K* (Figueredo et al. 2006). Most recently, they have introduced a psychometrically superior short form

called the *K-SF-42* (Figueredo et al. 2016a), having developed a novel method for creating cross-culturally valid and generalizable short forms. Empirical work using these and equivalent measures of life history strategies have found evidence that *K* is both a heritable (Figueredo and Rushton 2009) and temporally stable individual trait (Brumbach et al. 2009; Figueredo et al. 2014a); a recent meta-analysis has also shown that *K* influences a wide array of psychosocial traits (Figueredo et al. 2014b). According to Figueredo et al. (2013, p. 3), *K* has been empirically demonstrated to:

- (1) positively and significantly predict Executive Functions, Trait Emotional Intelligence, Mate Value Inventory, Mate Value Scale, Rosenberg Self Esteem Scale, Self-Adjective Checklist, Social Economic Exchange Scale, Collective Self Esteem Scale, Positive Assortative Mating, Female Physical Height, Long-Term Mating Sociosexual Orientation, Moral Intuitions, In-Group Loyalty, as well as Secure Attachment, Supportive Communication, and Long-Term Satisfaction in Romantic Relationships, both cross-sectionally and longitudinally; and (2) negatively and significantly predict the Mating Effort Scale, Short-Term Mating Sociosexual Orientation, Escalated Mate Retention Tactics, Affective and Punitive Responses to Sexual or Emotional Infidelity, Intimate Partner Violence, Interpersonal Aggression, Female Intrasexual Competitiveness, Disordered Eating Behavior, Negative Ethnocentrism, Negative Androcentrism, Levenson's Primary Psychopathy Scale, Levenson's Secondary Psychopathy Scale, Machiavellianism Scale, Buss-Perry Aggression Questionnaire, Proactive-Reactive Aggression Questionnaire, and General Social Deviance.

Controversies Surrounding the K-Factor The *K-Factor* has generated empirical interest across many substantive domains such as interest in babies (Zilioli et al. 2016) and across international contexts (reviewed in Figueredo et al. 2015). However, the *K-Factor* has also generated controversy from developmental life history researchers (Copping et al. 2014). Critics of the psychometric approach to life history are mainly concerned with statistical aggregation across measures, such as how ALHB is constructed (Copping et al. 2014), and are also concerned that these measures have not been adequately validated with biodemographic indicators of life history

(Copping et al. 2014). Critics have also asserted that statistical aggregation of higher-order life history factors may obfuscate developmental psychological sequences, obscuring possible inquiry into pathways that may shape the behavioral development of life history strategies across the life course (Copping et al. 2016). Professor Figueredo and his colleagues have defended the use of aggregated measures in cross-sectional samples as a “snapshot” of experiences and developmental milestones from that point in an individual’s life (Figueredo et al. 2015, p. 312). Accordingly, advocates of each position agree that both points of view indeed represent valid and complementary perspectives and have conceded to continue improving the measurement and development of measures that best accurately capture human life history strategies (Copping et al. 2016; Figueredo et al. 2015).

Environmental Harshness and Unpredictability Evolutionary models – particularly life history models – emphasize the important role the environment plays on intraindividual variation on different suites of traits (Stearns 1992). Extrinsic sources of illness, disability, and death in adulthood that are not accounted for by age or health status are purported to be major drivers in the evolution and development of life history strategies such that increases of extrinsic morbidity-mortality may accelerate life history strategies (Charnov 1991; Ellis et al. 2009). Professor Figueredo, along with Bruce Ellis and other colleagues (Ellis et al. 2009), examined the impact of adult extrinsic morbidity-mortality by proposing two distinct ecological constructs: environmental harshness and unpredictability. The American Psychological Association conferred the George A Miller Award for an Outstanding Recent Article on General Psychology upon this paper in 2010. According to this model, environmental harshness and unpredictability are independent drivers of life history evolution and development. Harshness at the population level is defined by increases in adult extrinsic morbidity-mortality and is usually often operationalized in modern human populations at the individual level by measures of low socioeconomic status (e.g., Simpson

et al. 2012) or exposure to violence (Brumbach et al. 2009). Unpredictability is defined at the population level as the amount of fluctuation in adult extrinsic morbidity-mortality and is operationalized in modern human populations at the individual level through measures of unpredictability such as the number of household or school relocations or family transitions (e.g., Simpson et al. 2012).

Current Research Activities Professor Figueredo and international team of collaborators are currently working on integrative models of social biogeography that follow the social *sequelae* of human life history at the population level in the achievement of higher levels of social harmony, macroeconomic complexity, aggregate productivity, and advanced cognitive development (Figueredo et al. 2016b). In addition, Professor Figueredo and colleagues have been developing a statistical model designed to disentangle the intrinsic gene-environment correlations in commonly used developmental data (such as parental, neighborhood, and economic sources of harshness and unpredictability) from truly extrinsic environmental influences.

Australopithecus africanus

Brian Villmoare

Department of Anthropology, University of Nevada, Las Vegas, CA, USA

Definition

First African hominin discovered; The species has several historically important specimens

Introduction

Australopithecus africanus is an early fossil hominin known from several localities in South Africa, most notably Swartkrans Cave. It is one of the most well-represented hominin fossil species, with large numbers of associated cranial and postcranial elements. Dating has proven difficult, due to the complex cave geology and lack of volcanic sediments in the known localities, but current estimates for this species range from 3.0 to 2.0 Ma (e.g., Herries and Shaw 2011).

History

This species includes several historically important fossils, most notably the juvenile specimen known as the “Taung child.” As described by Raymond Dart in 1925, this specimen represented the first known early African hominin and was confirmation of Darwin’s hypothesis that the earliest humans would be found in Africa. However, cultural and scientific prejudice, notably the wide acceptance of the fraudulent Piltdown specimen, prevented its acceptance as a human ancestor in the wider scientific community for almost 20 years. Various fragmentary specimens were discovered over the next several decades (e.g., Broom 1936), but it was not until the discovery of more complete adult specimens such as Sts 5 (aka Mrs. Ples, see Figure 1) at Sterkfontein (discovered 1947) that *Australopithecus*

Australopithecus aethiopicus

► *Paranthropus aethiopicus*

***Australopithecus africanus*, Fig. 1**

africanus was widely acknowledged as human (e.g. Clark 1950).

Anatomy

A. africanus is broadly similar to other known species of *Australopithecus*, in that it possesses several primitive apelike anatomical retentions, including, cranially, a projecting subnasal region, a notable canine root, a relatively flat cranial base, and a cranial capacity between 400 and 500 cc. There appear to be several anatomical specializations related to dietary adaptation in the face (the buttressing of the “anterior pillar” alongside the nasal aperture, Rak 1983) and teeth (overall large postcanine dentition, Broom and Robinson 1947), and a diet of relatively tough foods is therefore inferred. Postcranially, this species is also similar to other early hominins in the genus, with a body size ranging from 1.1 m (for inferred females) to 1.4 m (for inferred males), relatively long arms, a well-developed thumb, and clear evidence of bipedalism in the pelvis and lower limb. There is a sufficiently large sample to assign individual skulls to sex, and the range of known adult specimens (e.g., Sts 5 and Stw 505) indicates a relatively high degree of sexual dimorphism, consistent with other well-represented early hominins (e.g., *Paranthropus*, *A. afarensis*), and a gorilla-like social structure is therefore inferred.

Evolutionary Relationships

The phylogenetic position of *A. africanus* has changed over the last 50 years, as the fossil record, particularly from East Africa, has expanded dramatically. Until the 1970s, this species was seen as the best candidate for direct ancestry to all later human species, including both the genus *Homo* and the robust genus *Paranthropus* (e.g., Tobias 1978). However, currently, *A. afarensis* and *A. aethiopicus*, both from East Africa, are seen as the likeliest ancestors for those two genera, and *A. africanus* is typically relegated to a terminal side-branch of human evolution (Strait and Grine 2004). More recently, an analysis of dental morphology has proposed that *A. africanus* may be ancestral to the later South African species *A. sediba* (Irish et al. 2013).

Conclusion

Australopithecus africanus played a critical role in the acceptance of Africa as the location of the origin of human evolution. Anatomically, it is similar to other species in the genus, with many apelike retentions. The current consensus is that it represents a phylogenetic dead-end in the human tree, but the continued production of specimens at Sterkfontein and other sites means that this species represents a wealth of critical information on anatomical adaptations in early fossil humans.

Australopithecus boisei

► *Paranthropus boisei*

Australopithecus garhi

Brian Villmoare
Department of Anthropology, University of
Nevada, Las Vegas, CA, USA

Definition

Early human ancestor from 2.5 million years before present.

Introduction

Australopithecus garhi is an extinct fossil hominin species identified from remains discovered between 1990 and 1998 at the Bouri locality, in the Middle Awash region of the Afar Regional State, Ethiopia. The remains of this species, which date to roughly 2.5 Ma based on argon-argon dating techniques, are composed of unassociated cranial and postcranial elements discovered over

some 9 sq. km. Hypotheses for conspecificity for some of these elements are based on proximity at the time of collection; the more distant remains are associated primarily based on discovery in the same or temporally similar geological horizons.

Anatomy

The cranium (as known from holotype specimen BOU-VP-12/130) is characterized by extremely large postcranial dentition, well within the range of the robust group, *Paranthropus*, and it possesses a notable sagittal crest. However, this species lacks several anatomical traits uniquely seen in *P. robustus* and *P. boisei*, including molarization of the premolars, reduced anterior dentition, and a concave to flat midface; in fact the anterior dentition is notably large in this species. Other than the dental dimensions, *A. garhi* shows primitive anatomy typical *Australopithecus*: a ~ 450 cc cranial capacity, an apelike protruding subnasal region, and prominent canine roots. Postcranially, known elements (which were not discovered in direct association with cranial elements) demonstrate the characteristic *Australopithecus* pattern of relatively long arms; bipedalism is inferred, although there are no articular ends (which would allow more direct inference of locomotor pattern) preserved on the published femur.

Evolutionary Relationships

Phylogenetically, the position of *A. garhi* is unresolved. The initial publication (Asfaw et al. 1999) suggested the possibility of ancestry to the genus *Homo*, noting the lack of alternatives in the fossil record between 2 and 3 Ma. However, formal phylogenetic analysis has generally failed to support this hypothesis (e.g., Strait and Grine 2004), and subsequent discoveries have identified more likely alternatives for the ancestry of *Homo*.

Contemporaneous with Cutmarked Bone

Cutmarked bone, from several localities across several square kilometers, was found in general

stratigraphic association with the holotype cranium, and stone tools are known from the 2.6 Ma horizon at the Gona location, some 100 km distant (de Heinzelin et al. 1999). However, whether *A. garhi*, or another contemporaneous hominin, is responsible for this material, is not currently possible to demonstrate.

Conclusion

Australopithecus garhi is a hominin discovered in Ethiopia and dates to 2.5 million years before present. It is characterized by anatomy generally similar to other species of *Australopithecus*, but with notably large postcanine teeth.

Definition

A genus (or group of multiple genera) of fossil hominins ranging in geological age from the Pliocene through the early Pleistocene (~4.2–1.2 Ma = Mega-annum, or millions of years) of Africa, the name *Australopithecus* comes from Greek for “ape” (pithekos) and Latin “of the south” (australis), for the geographical location of the first material discovered, in South Africa.

Introduction

The *Australopithecus* group (“australopiths”) consists of up to twelve species of Plio-Pleistocene hominins (members of the human lineage following the phylogenetic divergence from chimpanzees and bonobos) mostly included in the genus *Australopithecus* (but several species are commonly included in a distinct genus, *Paranthropus*, and one species is named in a distinct genus, *Kenyanthropus*). Additionally, some researchers suggest that the earliest members of the genus *Homo* should actually be transferred to *Australopithecus*, leaving just *Homo erectus* and its descendants in *Homo*. The genus *Australopithecus* is almost certainly paraphyletic, meaning that it does not form a natural group; instead, one or more lineages are more closely related to members of other genera (e.g., *Paranthropus* or *Homo*). Australopiths were ape-like hominins that retained relatively small brains and probably some adaptations to the arboreal environment (i.e., long arms for tree climbing), yet were clearly upright bipeds (adapted to walking on two legs), some of which were primitive tool users. Determining which australopith lineage gave rise to later hominins (i.e., *Homo*) is a major area of focus and controversy in paleoanthropology (Fig. 1).

History

The genus *Australopithecus* was not the first hominin genus other than *Homo* to be named, but it is the oldest one that is still used (*Pithecanthropus*, for example, has been

Australopithecus Group, Fig. 1 Australopiths in time and space. Species are arranged according to their documented presence in the fossil record (x-axis; Ma = Mega annum: millions of years before present) and approximate geographic locality (y-axis; arranged from south to north). Species known from more than one locality or date, or when a range of dates is published, are shown with vertical and horizontal bars, respectively. Single points indicate that a species is known from one site and date; a dashed line indicates that the date is controversial

(as is the case with *A. prometheus*) or links material not currently assigned to a species to affiliated material (as is the case with the Ledi-Geraru mandible and the A.L. 666-1 palate, the earliest *Homo* material). *Homo* material <2 Ma is not shown but is represented in both East and South Africa and elsewhere outside Africa. Color codes indicate different genera: green *Ardipithecus*, black *Australopithecus*, blue *Kenyanthropus*, purple *Paranthropus*, red *Homo*

subsumed within *Homo* as *H. erectus*). Named in 1925 by Raymond Dart, *Australopithecus africanus* was immediately challenged by Dart's senior colleagues in England, largely due to the influence of the later-discredited Piltdown material and the early developmental age of the *A. africanus* type specimen, a juvenile skull from Taungs. Throughout the 1930s and 1940s, Robert Broom amassed a number of adult specimens that he initially attributed to a new species, *A. transvaalensis* (then later a new genus, *Plesianthropus* – “near man”), the most famous

of which is the Sts 5 cranium, nicknamed “Mrs. Ples.” Broom and his assistant John Robinson, who carried on work at Sterktontein after Broom's death in 1951, also discovered Sts 14, the first partial skeleton of an early hominin that preserved numerous associated postcranial (below the skull) bones and therefore provided information on the way in which *A. africanus* walked. Robinson (1972) and later Owen Lovejoy and others (e.g., Lovejoy et al. 1973) studied this material to understand the anatomy and biomechanics of bipedalism in an early hominin. The new, adult material

attributed to *A. africanus* mostly put to rest the idea that Dart's "African ape of the south" (or "southern ape of Africa") was anything but a bipedal, early member of the human lineage.

Additionally, Broom discovered what he considered two species of a new genus that he named *Paranthropus*, meaning "alongside man" (*P. robustus* and *P. crassidens*; although a minority of researchers today still recognize material from Kromdraai and Swartkrans, respectively, as separate species, the latter material is generally subsumed within the former species). These craniodentally (concerning the skull, including teeth) "robust" hominins were distinct from the more "gracile" *A. africanus*, which later led to the introduction and common use of "gracile and robust australopithecines" to refer to the two groups, the former later subsuming within it a new species called *Australopithecus afarensis* (see below). Today, the terms are outdated, both because neither *A. africanus* nor *A. afarensis* was particularly gracile in craniodental morphology and because "australopithecine" invokes a taxonomic statement (subfamily designation) that is considered by many to be too broad and therefore inaccurate (i.e., "hominin" refers to a tribe, Hominini, whereas Homininae, a subfamily, includes all African great apes – hominins and members of the chimpanzee/bonobos and gorilla lineages). Therefore, the term "gracile" has been largely abandoned and "robust australopith" is preferred in colloquial reference to members of the genus *Paranthropus*. In the 1950s, Louis and Mary Leakey discovered Olduvai Hominid 5 (OH5), a cranium belonging to what they called *Zinjanthropus boisei* ("Boise's eastern African man"), a hyper-robust species clearly adapted to heavy/tough/repetitive chewing, and hence nicknamed "Nutcracker Man."

In 1962, Sherwood Washburn organized a Wenner-Gren Foundation-funded meeting of prominent paleoanthropologists, primate anatomists, molecular anthropologists, primate behavioral ecologists, and the three primary leaders of the modern synthesis of evolutionary biology, George Simpson, Theodosius Dobzhansky, and Ernst Mayr, to discuss the current state of taxonomy in the human fossil record. While all of the

entries in what would become an edited volume (Washburn 1963) are now considered classic contributions, Mayr's paper on the taxonomy of fossil hominids had a particularly strong influence on what Washburn called the "new physical anthropology." Recognizing the surfeit of genera in the hominin fossil record, Mayr recommended that just two be recognized, *Australopithecus* (including *Plesianthropus*, *Paranthropus*, *Zinjanthropus*, and other genus names proposed for early hominins) and *Homo* (including archaic – e.g., Neandertals – and modern humans and a plethora of other genus and other species names now referred to as *Homo erectus*). Many paleoanthropologists followed suit, including Robinson, who sunk *A. africanus* into *Homo* but retained *Paranthropus*, thus adopting a distinct, two-genus system to that proposed by Mayr (Robinson 1972).

In the 1970s, discoveries in East Africa, specifically from Laetoli in Tanzania and Hadar in Ethiopia, led to the naming of a new species of *Australopithecus*, *A. afarensis* (although for taxonomic reasons some researchers prefer the genus *Praeanthropus* – "pre-man"). The material it was based on included the type specimen, a mandible from Laetoli (Laetoli Hominid 4; LH 4) discovered by Mary Leakey and her team, and a partial skeleton from Afar Locality 288 (A.L. 288-1) colloquially known as "Lucy," along with other craniodental and postcranial material from nearby localities (e.g., A.L. 129), discovered by Donald Johanson and Maurice Taieb. Since the naming of *A. afarensis*, much more material has been discovered, including the A.L. 333 "First Family," a collection of craniodental and postcranial fossils attributable to a group of individuals killed around the same time, A.L. 444-2, a large partial skull (Kimbel and Deleze 2009), and DIK-1-1, the skull and partial skeleton of a young individual similar in developmental age to the Taung child, from Dikika, Ethiopia (Alemseged et al. 2006). *A. afarensis* is both geologically older (3.9–3 Ma) and morphology more primitive in some ways than *A. africanus* (3.0–2.1 Ma); thus, it was interpreted by Johanson and Tim White to be ancestral to an *A. africanus*-*Paranthropus* lineage on one hand, and the genus *Homo* on the other (Johanson and White 1979).

The discovery of the KNM-WT 17000 (“the Black Skull”) cranium from West Lake Turkana in Kenya can be interpreted as a challenge to Johanson and White’s phylogenetic hypothesis (Strait and Grine 1997). Initially named *Australopithecus boisei* (Walker et al. 1986), it was later subsumed into the species *Paranthropus aethiopicus* based on a unique combination of features that were in some ways primitive (*A. afarensis*-like: e.g., very small braincase and a prognathic, or jutting face, as opposed to the flat, “dished” face of *P. robustus* and *P. boisei*) and in others derived (*P. boisei*-like: “robust” features of the skull, including a wide face and a sagittal crest, a protrusion of bone along the midline of the skull). If *A. afarensis* was ancestral to *P. aethiopicus*, which was in turn ancestral to *P. boisei*, then *A. africanus* was freed from its phylogenetic position between *A. afarensis* and *Paranthropus*. An analysis of nasoalveolar (nasal and upper jaw) morphology also supports the monophyly (ancestral-descendant relationship) of all *Paranthropus* species to the exclusion of *A. africanus* (Villmoare and Kimbel 2011).

Multiple new species have been discovered and named throughout the 1990s and 2000s, falling geologically and phylogenetically on both sides of *A. afarensis*. White and colleagues discovered new craniodental and postcranial material at Aramis in Ethiopia and named a new species, *Australopithecus ramidus*, which was later transferred to a new genus, *Ardipithecus*, based on its distinct and more primitive traits. *Ardipithecus ramidus* is now known from a partial skeleton and a plethora of other specimens (White et al. 2009). Another new species, *Australopithecus anamensis*, is additionally thought to be more primitive and potentially ancestral to *A. afarensis*. Specimens later attributed to *A. anamensis* were initially discovered in the 1960s at Kanapoi in Kenya. New material discovered in the 1980s and 1990s, including both craniodental and postcranial fossils, led Meave Leakey and her team to name the species in 1995 (Leakey et al. 1995). White and his team working at Aramis and Asa Issie in Ethiopia discovered new material that they attributed to *A. anamensis*, including jaws and a femur

(White et al. 2006). *Ar. ramidus* and *A. anamensis* date to 4.4 and 4.2–3.9 Ma, respectively, and form what White and colleagues describe as an ancestor-descendant relationship (White et al. 2006). In South Africa, a nearly complete skeleton from Sterkfontein nicknamed “Little Foot” (StW 573) was recently re-dated to ~3.7 Ma (Granger et al. 2015); if correct, it represents the oldest material in South Africa and is contemporaneous with *A. afarensis*. Its discoverer, Ron Clarke, has resurrected Dart’s species name for *Australopithecus* material from the South African site of Makapansgat, *A. prometheus*.

Other new species, either contemporary with or post-dating *A. afarensis*, include *A. barelghazali* (Brunet et al. 1995) in Central Africa (Chad, 3.6 Ma), *A. garhi* (Asfaw et al. 1999) and *A. deyiremeda* (Haile-Selassie et al. 2015) in Ethiopia (2.5 and 3.4 Ma, respectively), and *A. sediba* (Berger et al. 2010) in South Africa. The latter species is the best known, represented by two partial skeletons from Malapa (Malapa Hominin 1, or MH1, and MH2, 2.0 Ma), along with additional material from multiple other individuals. Both *A. garhi* and *A. sediba* have been argued to be the sister taxon (most closely related and sharing an exclusive relationship) to the genus *Homo* but neither is universally supported. A third new taxon, *Kenyanthropus platyops* (“flat-faced man from Kenya”), was named by Meave Leakey and colleagues in 2001 and also proposed as a candidate for that phylogenetic position (Leakey et al. 2001). Represented by a nearly complete but damaged cranium from West Turkana (KNM-WT 40000), the cranium is argued to share derived traits with members of the genus *Homo*, including a flat face with a non-jutting jaw.

One major problem stems from the relative ambiguity of the genus designation and how to decide what defines a particular genus. Bernard Wood and Mark Collard (1999) suggested that the earliest members of the genus *Homo* (*H. habilis* and *H. rudolfensis*) should be transferred to the genus *Australopithecus* based on an adaptive zone model, where factors like body size, diet, and locomotion separate species into *Australopithecus*

and *Homo*. This requires both craniodental and postcranial fossils to assess, however, and adequate material is not available for most species. *A. sediba*, which is adequately preserved and argued to share derived traits of the skull, teeth, and postcranium with members of the genus *Homo*, retains relatively small body size and adaptations to climbing, so would be classified in *Australopithecus* under this system, whereas it might be subsumed in the genus *Homo* or placed in a new genus under a strict, cladistic (i.e., character and parsimony-based) analysis (Berger et al. 2010; Dembo et al. 2015).

Locomotion

One thing that is clear is that members of the *Australopithecus* group demonstrate unequivocal evidence for bipedal locomotion, unlike earlier potential members of the hominin lineage (e.g., *Sahelanthropus tchadensis*, *Orrorin tugenensis*, *Ardipithecus kadabba*). *A. anamensis*, *A. afarensis*, and *A. africanus* show derived features of the foot, knee, ankle, pelvis, spine, and cranial base consistent with adaptation to habitual bipedalism (Robinson 1972; Lovejoy 2005). These features include a non-grasping foot with an adducted hallux (in-line big toe) and a large calcaneus (heel bone), a flat ankle joint, a large plateau at the knee joint, valgus (inward) angle of the femora, short and curved blades of the pelvis, sigmoidal curvature of the vertebral column with both thoracic kyphosis (posterior curvature) and lumbar lordosis (anterior curvature), and an anteriorly positioned, horizontally angled foramen magnum (“big hole” at the base of the skull) through which the spinal cord passes. Additionally, the Laetoli footprints preserve trace fossil evidence of bipedalism in the probable hominin that made them, *A. afarensis* (Masao et al. 2016).

Much discussion has been devoted to the retention of primitive features in the postcranial skeleton of *A. afarensis* and its implications for climbing vs. terrestrial bipedalism in this species (see Ward 2002 for a review). Disagreement centers on the interpretation of these features as primitive, nonfunctional traits in a committed

terrestrial biped vs. retained adaptations to climbing. Suffice to say, it seems likely that *A. afarensis* was a committed terrestrial biped that could forage and take shelter in the trees (Ruff et al. 2016). Unexpectedly, *A. africanus* seems to be better adapted to climbing than *A. afarensis* (Berger 2002). This suggests that either *A. africanus* has become secondarily more arboreal or that it retains the primitive condition and *A. afarensis* is more derived toward terrestrial bipedalism, perhaps in convergence with later members of the genus *Homo*; recent work on early hominin calcaneal robusticity has been interpreted in support of the latter hypothesis (Prang 2015).

Brain Size, Body Size, and Sexual Dimorphism

The late Miocene putative hominin, *Sahelanthropus tchadensis*, and early Pliocene *Ar. ramidus* both have chimpanzee-sized brains, with cranial capacities ranging from 360 to 370 cc (cm³) and 300 to 350 cc, respectively (Zollikofer et al. 2005; White et al. 2009) (chimpanzees average ~366 cc; Grabowski et al. 2016). Members of the *Australopithecus* group are characterized by an average cranial capacity of ~450 cc, ranging from ~400 to 500 cc (Falk et al. 2000). For comparison, early members of the genus *Homo* have slightly larger brains (624 cc in *H. habilis*, but as low as 509 cc; ~750 cc for early *H. erectus*, but as low as 546 cc) (Grabowski 2016); however, *H. floresiensis* and the recently discovered species *H. naledi* overlap with the australopiths (426 cc and 465–560 cc, respectively) (Berger et al. 2015; Grabowski et al. 2016).

Early hominins also vary in body size, again with overlap between australopiths and some members of the genus *Homo* (e.g., *Australopithecus* average ~ 32 kg; *H. habilis* average ~ 33 kg) (Grabowski et al. 2016). Relative brain size is probably more relevant than raw brain size because brain size and body size are evolutionarily correlated and therefore have coevolved (Grabowski 2016). When body size is taken into account and an encephalization quotient (EQ) is

calculated by comparing observed brain size relative to predicted brain size given regression estimates on body weight, the difference between chimpanzees (EQ = 2.4) and australopiths (e.g., *A. afarensis*, EQ = 3.2; *A. africanus* = 3.8; *A. sediba* = 3.9) becomes more pronounced, and members of the genus *Homo* (except *H. floresiensis*, EQ = 3.8) become more distinct from *Australopithecus* (e.g., *H. habilis*, EQ = 5.0; early *H. erectus* = 4.6; later *H. erectus* = 6.0; modern *H. sapiens* = 7.6 (Grabowski et al. 2016).

Sexual dimorphism, differences in morphology (size and shape) between sexes of a single species, can only be estimated for reasonably well-documented extinct species. *A. afarensis* meets this criterion, but researchers do not agree on the degree of sexual dimorphism in this taxon (see Reno and Lovejoy 2015 for a recent review and perspective on new material), although it is almost certainly greater than that observed in modern humans. Given this non-consensus and lack of a clear relationship between sexual dimorphism (in body size or canine size) and sociosexual system amongst primates, little can be said about australopith social groups at this time.

Tool Use

Darwin proposed that bipedalism evolved in the context of freeing of the hands for tool and weapon use; however, until recently, the oldest tools in the archaeological record (the Oldowan) were 2.6 Ma, greatly postdating the emergence of the hominin lineage and thought to be associated with either early *Homo* or *Paranthropus*. Newly discovered, more primitive stone tools from West Turkana, Kenya (Lomekwi 3), dated to 3.3 Ma (Harmand et al. 2015) suggest that earlier species of *Australopithecus*, or perhaps *K. platyops*, which was discovered nearby, were tool users. It is notable that bone tools may have been used by *P. robustus* for activities like digging (e.g., termite mounds; Backwell and d'Errico 2001); similarly, other non-stone materials such as wood and bamboo may have been used by early hominins but would be unlikely to preserve in the fossil record.

Conclusion

Australopiths are a group of Plio-Pleistocene hominins with a large temporal and geographic distribution, ranging over 3 million years (>4–1 Ma) throughout East and South Africa and into Central Africa. In addition to *Australopithecus*, other genera are often included in the group or even subsumed within *Australopithecus*, including *Paranthropus*, *Kenyanthropus*, and arguably *Ardipithecus*. The group is clearly paraphyletic, that is, it is not a natural group because at least some lineages are more closely related to the genus *Homo* (e.g., *K. platyops* or *A. sediba*). Future fossil and archaeological discoveries will undoubtedly both clarify and complicate our understanding of relationships amongst the *Australopithecus* group of hominins.

[Autism spectrum disorder \(ASD\)](#)

Definition

Autism is classified as a neurodevelopmental disorder with three common characteristics: impairments in social functioning, impairments in communication, and restrictions in behavioral repertoire or repetitive behaviors. The definition of autism has changed over time and is still controversial. Currently, the DSM V calls for a diagnosis of “Autism Spectrum Disorder” (or ASD) for people who previously would have fallen into any of three categories in the DSM IV. Those categories included (a) autism, (b) Asperger’s Syndrome, and (c) Pervasive Developmental Disorder-Not Otherwise Specified.

Introduction

When the movie “Rain Man” came out in 1988, there was a scene in which a medical professional was so unfamiliar with the term that he assumed that Tom Cruise’s character Charlie Babbit had said “artistic.” Clearly, autism had not yet really penetrated the cultural consciousness. Since then, autism has been a topic of increasing interest to people in the areas of clinical psychology, behavioral therapy, governmental policy, behavioral genetics, and medicine. There has been a large push to understand the disorder and to improve the quality of life of people with autism spectrum disorders. To the cognitive and evolutionary psychologists, the study of autism has been an illuminating endeavor which is helping us to

understand the social functions of the typical and atypical brain. This entry briefly covers how autism is identified, how it has increased in prevalence, how it can help evolutionary and cognitive psychologists understand neural organization via theoretical models, and some current issues affecting the autism community today.

Identifying Autism

There is no single symptom that can be used to identify a person with autism, and the impairments are usually recognized as a somewhat idiosyncratic pattern within a person. No particular deficit associated with autism, be it social, communicative, or behavioral, is guaranteed to be clearly present in a given person with autism. Generally, the characteristics that are seen as typical in autism are not clearly or sharply demarcated from the behavior of neurotypical people, which often makes it difficult to identify whether a person is properly identified as having autism, or has more mild, autism-like social or communicative impairments.

Increasing Prevalence of Autism

In 1943, Leo Kanner was the first to describe autism as a distinct syndrome. It was referred to as “childhood schizophrenia” before being called “infantile autism” and then just “autism” before being replaced by “autism spectrum disorder.” Incidences of autism were quite rare for decades, and even by 1975 it was estimated that only 1 in 5000 individuals were diagnosed with autism. A great deal of attention has been paid to a so-called autism “epidemic,” since the number of diagnosed cases of autism have risen dramatically in the past few decades and rates currently stand at about 1 in 68 (Weintraub 2011). However, it is unclear that this indicates a difference over time in the actual rate of autism in the population. More individuals are being diagnosed thanks to looser diagnostic criteria, increased awareness and acceptance, and the presence of programs designed to help autistic individuals (Fombonne

2009; Wing and Potter 2002). While heredity certainly accounts for a great deal of the reason some people have autism while others don’t, the leftover environmental variance is largely unexplained. However, it is always important to note that vaccination, in any format or vaccination schedule, has failed to be linked in any way with autism (DeStefano et al. 2013).

Interest to Evolutionary Psychologists

Autism is of special interest to evolutionary psychologists because it highlights the modular nature of social cognition and its dissociation from other functions (including general intelligence). Asperger’s Syndrome, specifically, is a category of ASD in which development in communication is not delayed and general intelligence is often unimpaired. Nevertheless, the person with Asperger’s syndrome may report being confused and bewildered by the social world. While everyone else seems to know what to do based on subtle social cues contained in tone of voice, body language, or subtext, the person with autism is often oblivious to nonliteral messages and is unable to act in a way that someone might if they were intuitively responsive to those signals. Simon Baron-Cohen has termed this phenomenon “Mindblindness.”

Therefore, a person with autism who is intelligent and communicative can allow for a very revealing comparison to neurotypical populations. By comparing the tasks on which a person with autism is (and is not) impaired, psychologists can learn more about the modular structure of the neurotypical brain.

In general, people with autism show a deficit on traditional “false belief” tasks, where a participant is asked to predict what a person will do when that person is acting based on an untrue (or out-of-date) belief or assumption. Interestingly, this impairment seems to be specifically about the minds of others and not out-of-date information *per se*. In one task, Leslie and Thaiss (1992) demonstrated that children with autism performed on par with their neurotypical peers when predicting behavior based on an out-of-

date photograph. This led the researchers to the conclusion that there was something about the ability to appreciate representations *in the head* of other people that was specifically impaired in autism. The brain module responsible for such functions was later termed the “Theory of Mind Module” or ToMM.

If such a module exists, it is important to know what is included in the proper domain of that module. More recent evidence has indicated that people with autism do not necessarily struggle with interpreting eye gaze or appreciating the basic desires and intentions of others. However, more complex or “higher order” social calculations like interpreting more cryptic desires or reading an emotion from facial cues are likely to elude a person with autism.

Alternative Cognitive Models for Autism

In addition to theories that focus on the dysfunction of a module specifically for Theory of Mind, other researchers have proposed that at least some of the deficits observed in autism are the result of impaired executive function (Kenworthy et al. 2008), or perhaps a lack of ability to integrate sensory information into a cohesive view of the world (Happé and Frith 2006).

Current Issues

The search continues for environmental factors which contribute to cases of autism. Within the autism community, there is some disagreement regarding whether this search for a cause and cure is really the best use of resources, or whether the focus ought to be in helping those with autism lead the most productive and satisfying lives possible.

Conclusion

Autism (also known as “autism spectrum disorder”) is a diagnosis involving communication,

social, and behavioral deficits. Its origins are not well understood, nor are its causes. Autism awareness has grown immensely over the last few decades, as have rates of diagnosis, but it is as yet unclear whether this is because more people actually have the symptoms of autism, or whether awareness, acceptance, and changing diagnostic criteria are the reason why so many people meet the criteria for autism spectrum disorder.

Avian Sperm Competition

Tomáš Albrecht

Definition

Sperm competition arises when a single female mates with more than one male. In such cases, post-copulatory processes involving sperm-sperm competition may represent an important component of sexual selection.

Introduction

Social monogamy is the prevailing mating system among birds, with males sometimes providing a substantial proportion of parental care. Until quite recently, therefore, polyandry was believed to be rare or absent in birds. Over time, however, there were growing indications that genetic polyandry does indeed occur in birds. Evidence came from a range of sources, including behavior (female

pursuit for extra-pair copulations, direct observation of extra-pair copulations in the field, males guarding females during the fertile period) and/or sex-biased heritability of morphological traits or plumage coloration (Griffith et al. 2002). The advent of molecular tools for determining paternity has revolutionized our understanding of genetic mating systems in birds. It is now apparent that genetic polyandry is relatively common in this group.

Extra-pair Paternity in Birds

The first DNA-based molecular study on multiple paternity in a free-living organism focused on house sparrows (Wetton et al. 1987). Since the late 1980s, more than 30,000 offspring of around 200 avian species have been screened for paternity status. It soon became obvious that the risk of sperm competition (often measured as the level of extra-pair paternity; EPP) varies considerably among bird species. Despite being common in many populations, EPP is completely absent in at least 10% of avian species (Griffith et al. 2002). In a typical socially monogamous avian species, about 11% of offspring result from extra-pair behavior. It is worth noting that, although molecular determination of paternity helps assess the risk of sperm competition, this value may actually underestimate both the frequency of extra-pair copulation and the risk of sperm competition in avian populations as not all extra-pair copulations result in extra-pair fertilizations. Attempts to explain interspecific variation in EPP levels have identified phylogeny as an important factor determining the occurrence of EPP in birds. As an example, EPP appears to be comparatively common in passerines, a phylogenetic branch comprising more than half of all avian species, with the proportion of extra-pair offspring approaching 80% in some species (Griffith et al. 2002). Several other ecological (e.g., population density, migration status, latitude) or life-history correlates of EPP (often associated with phylogeny) have now been identified in birds.

Across species, the varying risk of sperm competition due to polyandrous mating by females is

associated with a number of morphological and behavioral adaptations. Although males generally lack external genitalia, in some groups (e.g., ducks and ratites) the phallus has evolved to transfer semen directly into the female reproductive tract. In songbirds, the cloacal protuberance (or promontory) appearing around male cloaca during the breeding season may provide a similar function. As in other groups, the size of the testes (measured during the breeding season) increases with increased levels of sperm competition across avian species, as does the proportion of sperm-producing seminal glomera within the testes (Birkhead 1998). These adaptations may provide an advantage over other males in terms of larger and more competitive ejaculates (particularly useful when sperm competition occurs). In general, ejaculates in highly promiscuous species (such as the polygynous Galliformes) are selected to be of high quality, whereas ejaculates in genetically monogamous species with relaxed or absent sperm competition (such as owls, falcons, or penguins) often contain a large proportion of abnormal or immature sperm. Mate guarding and frequent within-pair copulations are also typical of promiscuous avian species.

The morphology of the sperm itself is exposed to strong selection pressure after copulation. In birds, as in other internally fertilizing vertebrates, selection on sperm can occur through female choice ("cryptic female choice") or through male-male (sperm-sperm) competition. While the former remains little studied in birds due to obvious methodological issues, the latter has received much attention recently. There have been a number of studies on the evolutionary context of spermatozoa morphology and function in passerines, with results showing a positive association between extra-pair paternity, sperm speed, and sperm length across species (e.g., Kleven et al. 2009).

Female birds typically store sperm for some time (the duration often determined by the typical clutch size of the species) in sperm storage tubules (SSTs), located at the uterovaginal joint. For a given species, SSTs are typically three times longer than the sperm cell, indicating intimate coevolution between sperm length and SSTs (Birkhead

1998). As sperm must fit into the SSTs, balancing selection on sperm size should be stronger in species with a high risk of sperm competition. As a result, variation in sperm length around the species-specific sperm size optimum should be reduced. Indeed, there is a strong negative correlation between variation in sperm length across males of the species and typical EPP rate (risk of sperm competition) for the species, suggesting that this estimate can be used as a reasonable surrogate for sperm competition risk across passerine species (Albrecht et al. 2013).

Unfortunately, intraspecific studies are less convincing in identifying sperm traits associated with superior male fertilization success, although careful experimental studies have identified sperm length and velocity as traits affecting sperm fertilization performance in at least some species (Bennison et al. 2015). As mentioned above, female control over fertilization (cryptic female choice) remains a “black box” in studies of promiscuous mating systems in birds. A clear example of female control over fertilization has been demonstrated in waterfowl, however, where “cryptic anatomical mechanisms of choice” (dead-end sacs or fake vaginas) in females have evolved to control for the outcome of frequent forced copulations with unwilling males (Brennan et al. 2007).

One might ask how sexual promiscuity (sperm competition) evolved and how is it maintained in avian populations? The consensus is that EPP is adaptive for males in that, through promiscuous behavior, males may increase the number of sexual partners and their own fitness. The benefits of EPP to females are less obvious as an increase in the number of sexual partners typically has no effect on female fitness. Females may gain indirect benefits, however, in terms of high-quality offspring, which leaves open the possibility that EPP evolved to compensate for hasty or inaccurate choice of social mate. The potential indirect benefits of sperm competition in birds have been intensively studied over the past two decades, with mixed results and generally inconclusive evidence (e.g., Arnqvist and Kirkpatrick 2005).

On the other hand, promiscuous behavior also carries potential costs to one or both sexes. As an example, males may be able to reduce parental care in response to female infidelity, which could constitute strong selection pressure against female promiscuity (Arnqvist and Kirkpatrick 2005). Indeed, EPP is almost absent in avian clades where males are largely responsible for food delivery to incubating females and growing offspring (e.g., in birds of prey or owls). Numerous other potential costs have been associated with promiscuous behavior, and these are reviewed in Forstmeier et al. (2014). This has led some to consider female promiscuity in birds to be a nonadaptive behavior evolving as a by-product of strong selection on promiscuous behavior in males (intersexual antagonistic pleiotropy or the “genetic constraint” hypothesis). Though a controversial idea, it has recently received solid experimental support (Forstmeier et al. 2011). Nevertheless, it remains difficult to explain why females in some species pursue extra-pair matings, despite the low strength of selection on male extra-pair paternity (contribution of EPP to overall male fitness) in these species. Despite intense research into this enigmatic behavior over the last three decades, there is still no general agreement as to whether promiscuity evolved as a male or female strategy in birds.

Conclusion

The risk of sperm competition varies substantially across avian species, making this group an ideal subject for studies on the evolution of behavioral, physiological, and morphological adaptations, as well as for assessing the potential benefits to female of genetic polyandry. Social monogamy is the prevailing mating system in birds and, from a sociobiological point of view, studies on the factors affecting postcopulatory processes in avian promiscuous systems could increase our understanding of human reproductive systems and behavior, particularly as most human cultures also promote social monogamy.

Definition

Humans have evolved strategies that helped them remove group members who hampered group efficiency. By labeling characteristics and behaviors, also known as stigmatizing, groups could identify and remove inefficient and undesirable group members. To avoid social rejection, our ancestors developed ways to avoid stigmatization.

Introduction

We all know him. The guy who wears unusual clothing, or maybe talks a little too loud. He gives innocent people dirty looks, leading others to reject him. Nobody wants to be “that guy.” No matter who it is, he has some characteristic that leads people to avoid or ignore him. People learn to identify this stigmatizing feature and, if they also have it, how to conceal it. Avoiding stigmatization helps people avoid numerous negative consequences, such as social rejection.

Stigmatization

In our evolutionary history, forming groups and lasting relationships gave our ancestors an upper

hand. By forming groups, our ancestors were able to rely on others for protection, resources, and reproductive needs (Kurzban and Leary 2001). Small groups provide tremendous advantages. However, as group numbers increase, so do the risks. Referring to living in groups, Alexander (1974) stated, "There are automatic and universal detriments, namely, increased intensity of competition for resources, including mates, and increased likelihood of disease and parasite transmission" (p. 328). To combat these threats, people need to identify inefficient and undesirable members in order to reduce the group to a manageable size.

The most desirable group is one in which group members equally contribute to shared goals. Those who do not contribute hurt the group and are viewed as a weak link (Turner 1982). To determine the weak links, a set of specific traits or characteristics are defined in order to segregate and remove those individuals. Anyone with that trait would be considered more of a cost than a benefit. This classification of individuals based on a characteristic is stigmatization (Kurzban and Leary 2001). Stigmatized characteristics can be based on whether an individual identifies with an outside group, such as racial, ethnic, or religious groups (Kurzban and Leary 2001).

The possession of a stigma informs group members that you lack the abilities required to perform the tasks necessary for group survival. Once marked, groups turn to denigration in order to look superior and force the lesser out (Turner 1982). In turn, the stigmatized individual will become rejected by the group. To avoid the stress and discrimination, stigmatized individuals will isolate themselves before rejection, only interacting with those in which they feel normal (Becker 1981). However, a stigmatization does not always mean instant rejection.

The amount of control a person has over a stigmatizing factor is correlated with negative attitudes and behaviors towards that individual (Mehta and Farina 1997). The more perceived control over the characteristic, the more the individual is discriminated against. For example, people often view obesity as something that people can control through diet and exercise. The

possibility of controlling one's weight adds to the ridicule and discrimination endured by obese individuals. Cancer patients, though stigmatized, do not face a similar fate due to the lack of control over developing the condition. Lack of control is not always a saving grace. The mentally ill and physically disabled are exceptions to that correlation (Mehta and Farina 1997).

Hiding Stigmas

Being linked to a stigma results in prejudice and discrimination (Kurzban and Leary 2001). To avoid ridicule and rejection, people try to hide the stigma. Some stigmas, like obesity, are difficult to hide. These individuals are forced to isolate themselves or attempt to cover their stigma to minimize the effects (Becker 1981). Once stigmatized, individuals will attempt to avoid further stigmatization. For example, because African Americans feel stigmatized, they show greater reluctance to seek medical attention for a stigmatizing medical condition (Anglin et al. 2006).

Some stigmas, however, are considered invisible. For example, some stigmas leave a psychological, rather than physical, mark on people, such as having a history of child abuse. An invisible stigma only becomes visible when people reveal it.

To try to keep stigmas invisible, there are three common tactics: counterfeiting, avoidance, and integration (Woods 1994). Counterfeiting involves pretending not to have the undesirable stigma. To make the cover story believable, individuals go to great lengths. For example, a diabetic child may eat and drink things that harm them in order to appear normal.

Counterfeiting involves creating a new identity. It also allows individuals to socialize with peers. On the other hand, avoidance entails telling half-truths, avoiding relevant topics, and censoring (Woods 1994). Though it is not an entirely new identity, individuals keep their distance from others, hiding their personal lives.

Both counterfeiting and avoidance shield people from being not being stigmatized, but they also come with consequences. Concealing a stigma

can lead to psychological strain, emotional stress, and stress-related illnesses (Smart and Wegner 2000). Fear and anxiety can increase these negative reactions (Smart and Wegner 2000).

The last tactic – integration – involves disclosing the stigma to peers. Disclosure can entail verbally informing everyone of the stigma, or even visually showing people the characteristic. For example, gay employees may tell their friends about their partner or bring their partner to work events. Though integration can provide relief, it also provides the risk associated with stigmatized people. That is, the reduction of stress through disclosure may lead to rejection. Because of these risks, individuals with invisible stigmas use varying strategies with different peers.

Controlling Stigmas

To avoid further stigmatization and rejection, people adapted the ability to control one's impulses, self-control (Baumeister et al. 2007). In a social interaction, controlling what one's says in order to hide their stigma requires a great deal of mental control. The stress and uncertainty of never knowing if your stigma will be discovered along with attempts to suppress negative stereotypes can be draining. For example, when African American students were primed with stigmatized thoughts, they showed lower self-control (Inzlicht et al. 2006). People placed in a stigmatizing situation for too long may become depleted, leading to poor self-control. Their poor self-control can lead to the discovery of their hidden stigma.

Conclusion

Nobody wants to be stigmatized. Being stigmatized can lead us to become socially rejected. Because we have a powerful need to belong, people evolved strategies to avoid stigmatization. Avoiding stigmatization is easier for some people than others. Visible stigmas often lead people to isolate themselves from the group, joining with others who make them

feel normal (Becker 1981). Stigmatized individuals will also do what it takes in order to avoid further stigmatization, even if it means avoiding doctor's visits (Anglin et al. 2006).

Other characteristics, such as AIDS or cancer, are easier to conceal. Though concealable, individuals are often left in a tough position. They risk rejection by disclosing it, but they also suffer from concealing their stigma. People avoid being stigmatized because they do not want to be rejected. Thus, we evolved the desire to avoid stigmatization.

[Burrhus Frederic Skinner](#); [Radical behaviorism](#)

Definition

B. F. Skinner (1904–1990) was an American psychologist who pioneered the field of behavior analysis and developed the philosophy of radical behaviorism. Skinner is widely known for his experimental work with rats and pigeons, the technologies that he developed (e.g., the operant conditioning chamber or *Skinner box*, schedules of reinforcement), and the philosophy of radical behaviorism, which underlies and unifies the basic and applied work of behavior analysts. He expanded the scope of his science and philosophy to issues of human culture and survival, spawning the application of his behavioral science to improve the human condition.

Introduction

At the heart of Skinner's contribution is *operant conditioning*, which focuses on the influence of consequences on behavior. As a tool to understand behavior, Skinner developed the concept of the *three-term contingency*, consisting of the antecedent, the behavior, and the consequence. The antecedent is the environmental condition prior to the occurrence of a particular behavior. When an organism behaves, it interacts with its environment, producing a stimulus change or consequence. When behavior is followed by certain consequences, the strength or probability of that response occurring in the future increases; this is the process of reinforcement. If the probability of behavior decreases following a consequence, the process of punishment is in effect. The three-term contingency occurs within the context of an individual's current state, with particular establishing operations (e.g., satiation, deprivation) influencing the consequences that will be reinforcing or punishing at a particular moment. See the ► [“Conditioning and Association”](#) entry for an additional discussion of operant conditioning.

For Skinner and the behavior analysts who follow in his tradition, the function of the behavior (i.e., the particular consequence that the behavior produces) is more important than the structure (i.e., topography) of the behavior. Indeed, *operant*

classes are sets of behaviors that have the same function. A great variety of topographically distinct responses can produce the same outcome, even with simple behaviors. Take, for example, a hungry rat in an operant conditioning chamber. In the chamber (the environmental setting), the rat can press a lever (behavior), which produces food (consequence). Although the rat can press the lever in a variety of distinct ways (e.g., with its paws, its nose, its flank), the act of depressing the lever and closing the attached microswitch is the same. Thus, the operant in this case is the lever press; any response that closes the microswitch can be reinforced by the contingent delivery of food to a previously food-deprived rat.

Sometimes, the behavior that increases in strength is not directly related to the production of the reinforcer. Skinner (1948) described this phenomenon as superstition, where a behavior is adventitiously reinforced, and the learner acts as if the behavior that they engaged in was causally related to the outcome. In his classic demonstration, Skinner provided access to food to a hungry pigeon on a time-based schedule, independent of the bird's behavior. The response that the pigeon happened to be engaging in at the time of food delivery (e.g., stepping, turning) was strengthened, especially with short inter-food intervals. Even though there was not a causal relation between the bird's behavior and the delivery of the food, the responses were still strengthened, similar to superstition in humans and other animals.

The principles of behavior analysis, including reinforcement and punishment, have cross-species generality. Following in the tradition of Watson (1913), behavior analysts embrace the idea of continuity of species, wherein the laws that govern the behavior of human and nonhuman animals are the same. Skinner (1984) suggested that the operant conditioning process supplements natural selection. Organisms that are able to learn based on the consequences of their behavior are more likely to survive than organisms that are not sensitive to such environmental changes, and the importance of learning may vary across organisms. Furthermore, the stimuli that organisms are likely to be sensitive to are biologically prepared.

For example, monkeys may be easily conditioned to show a fear of snakes, but not of flowers (Cook and Mineka 1989). Thus, the phylogenetic history of the species influences the stimuli that influences an individual's behavior.

The Darwinian model of natural selection suggests that the environment applies pressure on species. Given particular environmental conditions, certain organisms are more likely to survive (i.e., have a selective advantage) than others. With differential reproduction, the traits that were advantageous in that environment become more common in the population. Similarly, the Skinnerian behavioral tradition applies selectionist logic to behavior. Instead of focusing on the population of an organism, the radical behaviorist is interested in the population of behavior as the level of analysis. As particular responses are strengthened in a behavioral repertoire (i.e., become more common), other responses necessarily decrease in frequency. This process is exemplified in the process of shaping (e.g., Skinner 1951), wherein successive approximations of a response are differentially reinforced to produce an end goal.

Verbal Behavior

When at a dinner party in 1934, Skinner was faced with a challenge to use behavioral terms to explain why one of his dining companions uttered a particular sentence: *No black scorpion is falling on the table* (Claus et al. 2007; Skinner 1957; Palmer 2006). As a reply to this challenge, he published *Verbal Behavior* (1957), a book that describes the application of behavior analysis to language. Unlike other forms of behavior, verbal behavior is reinforced by the response of a listener, rather than by the direct action on the environment. Whereas the word serves as a common unit of analysis for linguists, the functional relations between the verbal responses are more important in verbal behavior. In this conceptual structure, verbal behavior can be organized by its type (e.g., mand, tact, interverbal), and the conditions under which these responses occur can be established scientifically.

Skinner's work was famously criticized by psycholinguist Noam Chomsky (1959). This book review has been described as overthrowing the behavior-analytic approach to language; Palmer (2006) suggested that some cognitive psychologists "embraced it as a kind of Emancipation Proclamation, a justification for rejecting the methodological constraints of behaviorism" (p. 256), and he described the review as an oft-cited initiating event for the "cognitive revolution" in psychology. As a reply, behavior analysts contend that Chomsky failed to understand Skinner's book and, therefore, drew erroneous conclusions (cf. MacCorquodale 1970) and that the "cognitive revolution" does not meet the standards of a scientific revolution (O'Donohue et al. 2003).

Despite the concerns that Chomsky raised about the ability for behavior analysts to adequately describe language, the approach Skinner developed has been highly influential in the field of behavior analysis. It has also been highly successful in teaching language skills to individuals with developmental disabilities, including autism. Skinner's approach to the functional units of verbal behavior (e.g., tacts, mands) allows for these components of behavior to be targeted for separate intervention, building increasingly complex verbal repertoires (Sundberg and Michael 2001). Fortunately for behavior analysts (and the individuals who have benefited from their approach to verbal behavior), their field was strong enough to survive an inflammatory book review (cf. Schlinger 2008).

The Philosophy of Behaviorism

In addition to the empirical work through which Skinner established the principles of operant conditioning and verbal behavior, he also developed the philosophy of radical behaviorism. Chiesa (1994) suggested that radical behaviorism produced "probably the most coherent philosophy of science in psychology today" (p. 7), underlying the science of behavior analysis, including the subdisciplines of the *experimental analysis of behavior* and *applied behavior analysis*. This conceptual systematization allows for clear

delineation of what behavior analysts study and the methods that they use.

The term *behaviorism* was first used by John Watson in 1913 to describe his new type of psychological science. The phrase *radical behaviorism* was used to contrast Watson's work as an extreme (i.e., radical) departure from other versions of psychology at the time (Schneider and Morris 1987). B. F. Skinner later used the term *radical behaviorism* to differentiate between the *methodological behaviorism* of John Watson. Since the mid-1960s, this was the most common label for Skinner's approach (Schneider and Morris 1987), and his 1974 popular press book, *About Behaviorism*, was devoted to making this philosophy more broadly understood. Whereas methodological behaviorism ruled out the influence of events that were not directly observable (cf. Watson 1913), radical behaviorism allowed such events to be considered, but instead considered them as behavior (e.g., Skinner 1945, 1974).

The philosophy of behaviorism allows a coherent science of behavior analysis to exist. This science emphasizes the importance of studying behavior as a primary topic of interest rather than as a proxy for some other events or structure (e.g., Chiesa 1994). The goals of behavioral science are to describe, predict, and influence or control behavior. To achieve these goals, certain philosophical assumptions must be met, including determinism, or the notion that given the same initial circumstances, only the same outcomes could occur. Whereas deterministic thinking is a given in sciences like physics or chemistry, it becomes more contentious when applied to the behavior of humans. A primary point of contention is the rejection of free will. In the behavioral perspective, the denial of free will means that behavior of all organisms (human and nonhuman) is caused by the individual's past experience and the contemporary environment. There is no room in a scientific analysis for causal factors beyond these two. If it was possible for the individual to respond based on free will (i.e., independently of their learning history), there would be no way to predict or control the behavior of those organisms, since any unexplained variability could be attributed to the will of the organism.

Beyond the reliance on determinism, or perhaps because of it, behavior analysts are pragmatic in their work. Following the philosophic tradition of William James, the *useful working* of procedures and philosophies is of great import to behavior analysts (Lattal and Laipple 2003). The pragmatic approach has defined the research agenda of behavior analysts and shaped their methodology. Interestingly, evolutionary psychologists also cite William James as an intellectual founder (e.g., Suplizio 2007), but the components of his work emphasized by each field differ. Whereas behavior analysts focus on environment-behavior relations, evolutionary psychologists seek psychological mechanisms related to survival (cf. Tooby and Cosmides 1989).

The focus on behavior defines the subject of enquiry in behavior analysis. With this approach, there is an emphasis on behavior of the individual, relying on single-subject or within-subject experimental designs (cf. ► [“Methods and Enduring Impact of Behaviorism”](#) entry). For any given organism, behavior analysts believe that behavior is a result of three primary factors: the evolutionary history of the species (phylogeny), the learning history of the individual (ontogeny), and cultural factors. Phylogenic factors influence the stimuli to which an organism might be sensitive and limit the responses that are possible. As much as a human might want to, they will never be able to fly on their own or see ultraviolet light without assistive technology. A parakeet, however, has a distinct advantage in both of these domains. The ontogenic history of the organism encompasses every experience that the organism has, including reinforcement and punishment. Based on their past experiences and the contemporary environment, an individual will act in predictable ways. Skinner suggested that he was not an originator of his behavior (or the science that he developed) but instead that he was a locus for contingencies and evolutionary history to come together to produce the outcome.

The third level of selection that Skinner (1984) described was the cultural practices of the group. This level applies uniquely to human behavior, which is highly sensitive to the behavior of others.

Cultural selection allows for the transmission of traits and behaviors across groups of unrelated individuals. Such transmission allows the development of educational practices, religion, scientific behavior, and other mechanisms that support human survival.

Social Applications of Behaviorism

With the ability to predict and influence behavior, Skinner saw the power of his behavioral technology to improve the human condition. He published several influential mass-market books to describe his ideas, including *About Behaviorism*, *Beyond Freedom and Dignity*, and *Walden II*. In these works, Skinner was able to reach a broad audience. A central theme of this work was the notion that society was failing in important ways and that the application of the science of behavior analysis could improve the world. The problems that Skinner described included issues of education, population growth, and the distribution of scarce resources. All of these problems reduced, to Skinner, to problems of human behavior. Without changing the way our species behaved, Skinner foresaw the dramatic escalation of these problems to the point where human survival would be threatened. He wrote, “The choice is clear: either we do nothing and allow a miserable and probably catastrophic future to overtake us, or we use our knowledge about human behavior to create a social environment in which we all shall live productive and creative lives and do so without jeopardizing the chances that those who follow us will be able to do the same” (1978a, p. 66).

In *Walden II*, Skinner described the application of behavioral technologies to create a society in which leisure is abundant, work is divided evenly, and resources are made available to everyone, i.e., *the good life* is achieved via careful planning and experimentation. Skinner (1978a) noted that the society that he describes involves minimal ownership of property and, therefore, had a lessened environmental impact than contemporary society. The goals in the society he described were to produce pleasant personal interactions via the

technology of behavioral science. Practices which this group uses, from education to government, are effective; if a practice does not work, it is abandoned, in an experiment of social design (Skinner 1978b). Although it was a work of fiction, the novel spawned several intentional communities, including Twin Oaks in Louisa, Virginia, and Los Horcones in Sonora Mexico. These communities put into practice Skinner's ideas presented in his novel (cf. Kincaid 1973), and they continue to exist today.

Following the initial work of Skinner, the application of behavioral technology to a wide array of important problems has expanded exponentially. Crime prevention, education, environmental sustainability, etc. all have benefited from the efforts of applied behavioral science (cf. Biglan 2015). His impact has been far-reaching, and his work has directly improved the lives of individuals around the world.

Conclusions

Skinner's contributions to psychological science, especially operant conditioning and the philosophy of radical behaviorism, provide a selectionist framework to understand behavior. This framework provides analogues between the Darwinian model of natural selection and the behavioral changes that occur within the life span of an organism. Skinner's analysis of verbal behavior greatly expanded the application of his science, despite the criticism it faced. His contributions provided the foundations for the science of behavior analysis, including the experimental analysis of behavior and applied behavior analysis. The ultimate goal of Skinner's science of behavior was to make the world a better place for its contemporary inhabitants and future generations via environmental interventions.

Bab-El-Mandeb Strait

Nicholas Primavera
SUNY New Paltz, New Paltz, NY, USA

Synonyms

[Mandeb Strait](#)

Definition

Refers to a strait of water located between modern-day Yemen on the Arabian Peninsula and the African countries of Djibouti and Eritrea.

Introduction

The Bab-el-Mandeb Strait is primarily used with regard to modern times as a means to transport large amount of oil via its connection to the Red Sea and the Suez Canal. According to the African origin of modern human's hypothesis, the Bab-el-Mandeb holds a significant role of importance in the dispersal from Africa.

The Bab-El-Mandeb Strait and its Evolutionary Importance

In order to understand the importance of the Bab-el-Mandeb Strait, it is imperative to have a basic understanding of the African origin of modern humans. The African origins theory, also referred to as the “Out of Africa Theory,” states that the early migration of modern humans, otherwise known as *Homo sapiens*, evolved and eventually the African continent. According to So and so, “Currently available genetic and archaeological evidence is generally interpreted as supportive of a recent single origin of modern humans in East Africa. However, this is where the near consensus on human settlement history ends, and considerable uncertainty clouds any more detailed aspect of human colonization history” (Liu et al. 2006). There are three primary variations of this theory, including the “Strong Garden of Eden,” or the “African Eve,” model which posits that after modern humans first emerged in Africa between 200–150 kya, they dispersed to other parts of the world after 100 kya and replaced all archaic hominins without any genetic admixture (Beyin 2011). The second potential variation is the “Weak Garden of Eden” which asserts that anatomically modern humans evolved in a restricted area of Africa sometime after 200 kya and dispersed to separate regions around 100 kya replacing all archaic forms. According to the latter model, each human population is thought to have passed through a bottleneck in their respective destinations and then recovered after favorable conditions returned. (Beyin 2011). The third and final variation of this theory “argues for multiple dispersals of early modern humans out of Africa. Originally posited by Lahr and Foley, this hypothesis recognizes three dispersal events in the Upper Pleistocene, and perhaps a fourth one recently proposed by Armitage” (Beyin 2011).

Regardless of which variation actually occurred, the first wave of dispersal took place around 130,000–150,000 years ago, while the second wave took place around 70,000 years ago. The second wave of migrants crossed the Red Sea via the Bab-el-Mandeb Straits. Although at the present time the Strait is approximately

20 km (12 miles) wide, 50,000 years ago the sea levels were significantly lower, thus making the Strait much narrower. If this theory was able to be proven, the Bab-el-Mandeb Straits would have seen the first major migration of modern humans. Furthermore, via its connection to the rest of the world, it would have allowed modern humans to spread to essential anywhere.

Conclusion

In conclusion, the Bab-el-Mandeb Strait should be considered a place of high evolutionary importance. If the previously mentioned theories are able to be proven true, then the Strait will have been the gateway for the spread of modern humanity.

Bait Fishing

Sarah Jelbert
Department of Psychology, University of
Cambridge, Cambridge, UK

Synonyms

[Active bait fishing](#); [Baiting](#)

Definition

The active placement or manipulation of edible or inedible items, to attract or distract potential prey, facilitating prey capture.

Introduction

Bait fishing is a rare form of tool use that has been observed primarily among herons (family

Ardeidae), as well as a small number of other water birds (Ruxton and Hansell 2011). It involves the placement of a buoyant object on the surface of a body of water, which serves to attract or distract fish, and potentially increases the chance of capturing prey when fishing. The objects used as bait are often food items – such as insects or bread – that are highly attractive to fish, but small inedible items, including sticks or feathers, can also be used. In clear instances of bait fishing, birds will bring items to the water that they found elsewhere (Lovell 1958), or they will keep the floating item within striking distance by actively repositioning the item before it drifts out of reach.

To date, although bait fishing has been observed in a number of different species, it remains an uncommon behavior. No individuals have been observed to rely solely on bait fishing to obtain food, and this behavior has only been observed in a proportion of individuals within a population. Analogous behaviors have been observed among a few other species of animal, where bait has been used to attract different types of prey (discussed in more detail below). These behaviors are most commonly described using the term “baiting” rather than bait fishing.

Bait Fishing by Water Birds

Bait fishing was first anecdotally observed and reported in the 1950s (Lovell 1958). Lovell, throwing bread to birds at a lake in Florida, observed a green-backed heron (*Butorides striatus*) fishing from a small wall. When Lovell threw bread toward the heron, the bird took the bread to the water’s edge, and then, rather than eating it, the heron placed the bread in the water. When the bread began to drift away the heron repositioned it closer to the wall. After a few moments Lovell observed a fish begin to nibble on the bread, and, suddenly, the heron successfully speared the fish. Lovell remained at the lake and observed the heron performing this behavior repeatedly over a number of days.

To date, bait fishing has been observed in the wild or in captivity among at least seven different

heron species, as well as two species of gull and one species each of kite, sun bittern, and kingfisher (reviewed in Ruxton and Hansell (2011) and Shumaker et al. (2011)), and reports of this behavior in additional species continue to amass. Bait fishing has been studied most extensively among the green-backed herons – in which the behavior was first identified – which have been observed to fish with bait in multiple locations around the world, including southern America, Japan, and parts of western Africa (Higuchi 1988). Note that green-backed herons are sometimes classified into two species (the green heron, *B. virescens* and the striated heron, *B. striatus*) but are now most commonly considered to be a single species.

The items that are used as bait appear to vary across locations. At sites studied in Japan, green-backed herons have been observed to use almost any nearby items as bait, including bread, popcorn, flies, insects, sticks, leaves, feathers, and berries (Higuchi 1986), while in other areas the items observed to be selected as bait have been more restricted. On a few occasions, herons have been observed to break a large stick into a smaller piece and then use this as bait, which can be considered a form of tool manufacture (Higuchi 1986; Shumaker et al. 2011). Given the differences that might exist in attracting fish, some researchers draw a distinction between bait fishing using edible and inedible items, referring to the latter as “lures” (Ruxton and Hansell 2011).

This bait-fishing behavior can be viewed as an extension of a more conventional fishing technique – the stand-and-wait method – where a predator remains stationary until prey comes within reach then delivers a rapid strike to capture their prey. In this context, provisioning bait is expected to increase the bird’s success, by enticing fish to swim within the bird’s striking distance more often than would occur without bait. However, although there are some indications that bait fishing can be an efficient technique, the prediction that bait fishing is more effective than alternative fishing tactics, not involving bait, has yet to be explicitly tested. In one of the most systematic observational studies, Higuchi recorded the success rate of adult and juvenile green-backed

herons engaging in bait fishing using a range of different baits and lures. Adult herons were highly successful when using flies as bait, catching a fish on 86% of observed attempts and on 56% of attempts when using other insects. In contrast they obtained a fish on only 29% of attempts using sticks and 25% when using berries, both items that were commonly placed onto the water by the birds. Juveniles were substantially less successful than adults, typically only placing inedible objects on to the water's surface (Higuchi 1986). These results demonstrate that fishing with edible bait was more profitable than using inedible lures, but it remains unclear how bait fishing compares to other fishing tactics. A detailed observational study of three herons indicated that considerable individual differences could be found in both the propensity to engage in bait fishing and the chances of success, which may have been linked to features of the birds' territories (Higuchi 1988). Thus, one possible explanation for the rarity of this behavior is that bait fishing may rarely be more effective than other fishing techniques (Ruxton and Hansell 2011).

Origins of Bait Fishing

Relatively little is known about the origins of bait-fishing behavior. It is plausible that passive bait fishing – where birds wait near bait or lures already present on the water's surface – could have acted as a precursor either behaviorally or evolutionarily to active bait fishing (Gavin and Solomon 2009; Lovell 1958). Other researchers have suggested that “dunking” behaviors, where food is dipped into water before it is eaten, could have preceded the placement of bait, by enabling a bird to form an association between placing items in water and the presence of fish (Ruxton and Hansell 2011). Given that bait fishing is rare, but has been observed in a number of different locations, it has likely arisen a number of times independently. Thus, this behavior may have a variety of different origins. Although some researchers have speculated that bait fishing requires special cognitive abilities (reviewed in Ruxton and

Hansell (2011)), much like other instances of tool use, there is currently no reason to believe that bait fishing depends on advanced cognition (Shumaker et al. 2011).

Baiting Behaviors in Other Species

In addition to the behavior of water birds, using bait to catch fish has also been observed among one group of brown capuchin monkeys, a species known for its wide range of tool-use behaviors (Mendes et al. 2000). Here, capuchin were observed to catch fish with their hands, and on several occasions an individual threw food items into the water, or held the food under the surface with one hand, potentially to attract fish. Analogous baiting behaviors have also been noted in a small number of other species (see Shumaker et al. (2011) for a comprehensive list). As one example, assassin bugs have been reported to use the carcasses of termites as bait to entice other termites out of their nests (McMahan 1982). Of particular note, burrowing owls have been observed to place mammalian dung close to their burrows, which appears to function as bait for dung beetles, a major component of these birds' diet (Levey et al. 2004). By experimentally manipulating the presence or absence of dung in front of a number of owls' burrows, Levey and colleagues demonstrated that the owls consumed far greater quantities of dung beetles when the dung was present, indicating that the dung does attract dung beetles. Burrowing owls regularly replace dung when it is removed, demonstrating that they engage in active baiting.

Recently, it has been suggested that crocodiles and alligators also perform a form of baiting. Dinets and colleagues report anecdotal evidence that crocodilians – residing in areas with large populations of egrets and other wading birds – often lie in shallow water with sticks positioned across their snouts (Dinets et al. 2015). On one occasion a crocodile was observed to catch an egret as it approached one of the sticks, suggesting that this behavior potentially functioned to attract birds seeking scarce nest material. In a systematic study, crocodiles were observed with sticks on

their snouts a number of times ($n = 11$ observations); however, the researchers did not observe birds attempting to take the sticks, nor did they observe successful predation of birds. Thus, whether this behavior is an example of baiting is not yet known.

Conclusion

In conclusion, bait fishing is a rare form of tool use, where buoyant items are actively placed by an animal on the surface of the water to attract or distract potential prey. This behavior has been most frequently observed among herons (*Ardeidae*), as well as in a small number other water birds. It can involve the placement of a range of different items to attract prey, with flies being one of the most successful types of bait. Analogous behaviors – often referred to as baiting – have been observed among other species, predominantly to catch invertebrate prey.

[Vestibular system](#)

Definition

The vestibular system of the inner ear contains various structures responsible to keep the person's balance and posture

Introduction

The balance system, otherwise called vestibular system, is a complex system with many structures. These are the bony labyrinth, the membranous labyrinth of the inner ear, the cerebellum, the eyes, the brain cortex, and the muscles and joints which connect to the brainstem known as the vestibular nuclei (Munir and Clarke 2013; Chang and Khana 2013).

The Vestibular System

The vestibular system contains two structures known as the macula and crista ampullaris; these are sensory neuroepithelium (Chang and Khana 2013). They consist of sensory mechanoreceptors called hair cells contained in a neuroepithelium membrane. Russel and Sellick (1978) are credited with being the first to study the mammalian inner cells. The job of these cells is to distribute the movements of the cochlea partition to the central nervous system for processing (Pickles 2012, p. 57; Chang and Khana 2013).

The basic structure of the hair cell is a single large kinocilium and about 100 stereocilia on its end (Chang and Khana 2013; see Pickles 2012, pp. 57–66). The structure of the kinocilium is that of a motile cilium with nine peripheral doublet microtubules and two central microtubules (Cuschieri 2009). The stereocilia are long microvilli organized in rows behind the kinocilium in a descending order. The polarity of the receptors is established by the kinocilium, and the stereocilia holds the sensory transduction. Deflections of the stereocilia in the direction of kinocilium opens ion channels that causes an influx of potassium and calcium ions and an efflux of sodium ions, causing depolarization of the receptor membrane. When the stereocilia are deflected in the opposite way away from the kinocilium, this action closes the channels and the receptor cells is hyperpolarized (Cuschieri 2009).

The Bony and Membranous Labyrinth

The bony and the membranous labyrinth is a part of the peripheral vestibular system. This complex balance organ of the inner ear contains the cochlea and the semicircular canals. It is filled with perilymph (Hain and Helminsky 2007), a substance that resembles the cerebral fluid, and it is used by the perilymphatic duct into the subarachnoid space (Chang and Khana 2013). The perilymph is contained in the space between the bony labyrinth and the membranous labyrinth (Pickles 2012). The membranous labyrinth contains sensory epithelium and surrounds the perilymph inside the bony labyrinth. There is a fluid called endolymph which is contained in the membranous labyrinth. This fluid is similar in composition to the intracellular fluid, and it is produced by the capillaries in the stria vascularis in the wall of the cochlear duct and is immersed by the endolymphatic sac (Chang and Khana 2013).

The membranous labyrinth also consists of the utricle, the saccule, and the lateral, superior, and posterior semicircular ducts. Each structure contains a sensory neuroepithelium called the macula. The macula's physiological property is adaptation. Therefore, when the head performs minor movements, the bent hair cells and the depolarized membrane potentials return to normal. The function of the utricle is to sense horizontal movement and the function of the macula of the saccule is to sense vertical movement. Both the utricle and saccule respond to linear acceleration, forces of gravity, and the minor movements of the head (Chang and Khana 2013).

Semicircular Canals

The semicircular canals partially embody the bony labyrinth (Munir and Clarke 2013). The structure of each semicircular canal is perpendicular to the other canals on the ipsilateral side and coplanar with the contralateral canals (Chandrasekhar 2013). The neurosensory elements of each canal are called the crista and the cupula and lie perpendicular to the plane of the canal (Chandrasekhar 2013).

The function of these three semicircular canals is to sense the turning motion of the head (Munir and Clarke 2013). The otolithic organs contained in the canals respond to the pull of gravity and provide mass to the hair cells of the balance system.

Vestibular Ganglion

Another structure called the vestibular ganglion, also known as Scarpa's Ganglion, is located in the lateral portion of the internal auditory meatus, and it is composed of approximately 20,000 bipolar cell bodies receiving afferent impulses from the hair cells of the crista ampullaris and the maculae (Chang and Khana 2013). According to Lorente de No (1926, 1931, as cited in Ballantyne and Engström 1969), the vestibular ganglion is consisted of five parts differentiated from each other on the size of their cells. These parts are called pars magnocellularis anterior; pars parvicellularis anterior; pars magnocellularis posterior; pars magnocellularis posterior; and pars parvicellularis posterior. The vestibular ganglion appears to be divided into a superior and inferior part united by an isthmus (Tascioglu 2005). The peripheral processes from the superior ganglion innervate the ampullary crests of the superior and lateral semicircular ducts and macula of the utricle, and the peripheral fibers from the inferior ganglion innervate the macula of the saccule (Tascioglu 2005). Also, the axons from the superior and inferior parts of the vestibular ganglion come together to form the vestibular nerve. In combination with the cochlear nerve, it becomes the vestibulocochlear nerve (Chang and Khana 2013).

Vestibular Nuclear Complex

Vestibular input is processed by the vestibular nuclear complex, which consists of four nuclei: medial, superior, lateral, and inferior (see Tascioglu 2005). This is the primary processor of any vestibular input.

It is noteworthy that the vestibular nuclei have four main connections: (1) connections with the ocular muscles; (2) connections with the Postural Back muscles; (3) cerebellar connections and; (4) connections with higher centers. These four connections constitute the Central Vestibular System (see Cuschieri 2009, for more info about these connections).

The Cerebellum

Moreover, the cerebellum is vital for the control of finer movement (Munir and Clarke 2013). The role of the cerebellum in the vestibular system is to function as an adaptive processor monitoring vestibular performance and to readjust vestibular input through inhibitory input as necessary (Chang and Khana 2013). The "vestibulocerebellum" (Chang and Khana 2013) is consisted of the flocculonodular lobe and the vermian cortex. Efferent information is received from the bilateral vestibular nuclei from the ipsilateral cerebellum. The projection fibers included in the cerebellum go directly to the ipsilateral vestibular nuclei and to the ipsilateral fastigial nucleus (Chang and Khana 2013). The axons from the fastigial nucleus project to the contralateral vestibular nucleus through the juxtarestiform body, an area that is significant in terms of postural reflexes and orientation (Chang and Khana 2013). The vestibulocerebellum controls body balance and posture and is linked to the ocular motor neurons (Cuschieri 2009).

The Cortex

The cortex is the part of the brain that is responsible for conscious awareness and the manipulation of space (Munir and Clarke 2013). However, specific information regarding complex cortical vestibular connections is not yet thoroughly explained nor is there a consensus of the location of a vestibular cortex (Chang and Khana 2013). Studies on humans have suggested that the main cortical processing region is most likely in or near the parietal or insular cortex (Chang and Khana

2013). Based on a conjunction analyses (see Lopez et al. 2012), it was found that the regions showing convergence between two stimulation methods were located in the median and posterior insula, parietal operculum, and retroinsular cortex. The right hemispheric parietal opercular area OP 2 was demonstrated to be the most consistent area of activation, based on a study from Zu Eulenburg et al. (2012). The authors further suggest that the cytoarchitectonic area OP 2 in the parietal operculum may represent the human homology to the vestibular area PIVC as proposed by Guldin and Grüsser (1998) in non-human primates.

Furthermore, signals from the cortex to the muscles and vice versa via the motor nerves are needed to maintain posture and balance. Additional visual stimuli from the eyes constantly inform the nervous system regarding motion in the environment (Munir and Clarke 2013). Specifically, the vestibulo-ocular reflex is at play, which helps to coordinate eye movement in order to stabilize retinal images while the head rotates (Chang and Khana 2013). The ocular muscles cause eye movement responding to stimuli from the brainstem (vestibular nuclei) as well as from the cortex in order to maintain focus while the head exercises movement. Information from all these structures is sent to the brainstem for processing regarding balance (Munir and Clarke 2013).

Alcohol and Balance

Alcohol intoxication has devastating results on the brain and the body. Postural sway is directly affected as well as the oculomotor system. Studies has shown that indeed alcohol interfere more with the synaptic transmission in the lateral vestibular nucleus (LVN) monosynaptic and polysynaptic II neurons (Nieschalk et al. 1999; Ikeda et al. 1980).

The deleterious effects of alcohol are further supported based on a research of Modig et al. (2012). In their study, they have found that, based on the dosage, postural control is affected, specifically latera motion rather than anteroposterior. They added that alcohol intoxication

decreases the adaptation mechanisms used for stability in lateral movement.

Specifically, the cupula in the semicircular canals becomes lighter than the endolymph leading to the process called the buoyancy hypothesis (Fetter et al. 1999). Fetter et al. added that alcohol intoxication causes a vertical velocity offset, which may be toxic to the central vestibular pathways, producing a tone imbalance of the vertical vestibulo-ocular reflex. There is also more reliance in visual information when alcohol is digested in high levels, as well as a decompensation of small subclinical vestibular asymmetries and a dysfunction of the otoliths (Hafstrom et al. 2007).

Conclusion

The main structures of the balance system (vestibular system) were explained. These contain the bony and membranous labyrinth which contains the cochlea and the semicircular canals. There is also the vestibular ganglion, also known as Scarpa's Ganglion, with its bipolar cells that contribute to keep the person's equilibrium. The cerebellum and the cortex are responsible to the control of finer movement and the perception and awareness of space. The intoxicating results of alcohol on balance have also been briefly reviewed.

Barbara Smuts and Robert Smuts

Melissa Emery Thompson

Department of Anthropology, University of New Mexico, Albuquerque, NM, USA

Introduction

Robert Smuts (1920–2003) and Barbara Smuts (1950–) are father and daughter scholars recognized for their interdisciplinary work in evolutionary psychology. Barbara Smuts has conducted research on social relationships and social cognition in primates and other species. Robert Smuts conducted historical research on women's labor participation and later contributed to theoretical discussions on sex roles within evolutionary psychology. The two scholars worked together at the University of Michigan and collaborated to produce a seminal paper on the evolution of sexual coercion.

Barbara Smuts

Barbara Boardman Smuts is a biologist and anthropologist whose research has addressed the evolutionary significance and proximate maintenance of social relationships in primates, canines, and cetaceans. She received her B.A. in anthropology from Harvard University in 1972 and her PhD in neuro- and biobehavioral sciences in 1982 from the Stanford University Medical School and continued at Stanford as a fellow at the Center for Advanced Study in the Behavioral Sciences. She served on the anthropology and psychology faculty at the University of Michigan between 1984 and retirement in 2013. After retirement, she continues to conduct research on social behavior in domestic dogs.

Smuts established her early career as a primate behavioral ecologist. After receiving undergraduate training from evolutionary anthropologist Irvén Devore and evolutionary biologist Robert Trivers, she conducted a doctoral research study of male-female social relationships in a troop of wild olive baboons (*Papio cynocephalus*) in Gilgil, Kenya. This 2-year study culminated in the publication in 1985 of the book *Sex and Friendship in Baboons* (Smuts 1985). This was among a handful of texts that formed the foundation of modern primatology by applying rigorous data collection and analysis methods while maintaining important elements of an ethnographic approach. Smuts documented the special social relationships, or “friendships,” that formed between female baboons and one or more males in their groups. Males protected female friends and their offspring from attacks by other individuals and, in turn, received preferential mating access to the females. These findings emphasized a role for female choice and alternative male mating strategies in a system typified by male-male competition, stimulating broader interest in the complexities of primate social relationships. These findings, and later research on other primates, have spurred continuing research and debate into whether males form friendships with females and their young as parenting investment, in order to protect offspring that they may have sired; as mating investment, in order to increase their chances of mating with the female in the future; or both. Smuts and David Gubernick produced an important comparative analysis on this issue, outlining predictions for both paternal effort and mating effort hypotheses and arguing that paternity certainty alone is an inadequate predictor of male interactions with infants across species (Smuts and Gubernick 1992). Smuts published additional articles on her field studies with baboons, including analyses of gestural communication (Smuts and Watanabe 1990) and reproductive rates (Smuts and Nicolson 1989). She collaborated with co-editors Dorothy Cheney, Robert Seyfarth, and Richard Wrangham on the comprehensive text *Primate Societies* (Smuts et al. 1987), a taxonomically based review of social behavior in primates which is widely

implemented as a text in undergraduate anthropology and psychology courses. Linking her interests in primatology and human behavior, Smuts also coauthored a transformative paper on *The Human Community as a Primate Society* (Rodseth et al. 1991), which identified key evolutionarily derived features of human social organization by positioning humans within the context of primate socioecological diversity.

In evolutionary psychology, Smuts is perhaps best known for a series of influential papers advancing an evolutionary perspective on male aggression against females. A 1992 paper used comparative evidence from primates to propose an evolutionary perspective on male violence against women (Smuts 1992a). Smuts argued that many forms of intersexual aggression function to facilitate male reproductive strategies via the control of female sexuality. By viewing sexual violence as an evolutionary phenomenon rather than merely as a social problem, Smuts was able to generate a number of testable predictions about the prevalence of coercive behavior across human societies, suggesting potential countermeasures. A 1993 paper, coauthored with her father Robert W. Smuts, provided a comprehensive evaluation of the potential sexually selected functions of male aggression against females, along with female counter-strategies, in a wide range of mammals (Smuts and Smuts 1993). This paper provided an operational definition of sexual coercion and argued for the recognition of sexual coercion as a third form of sexual selection. In 1995, Barbara Smuts extended this framework to argue that male incentives to control female sexuality underlie the origins of patriarchy (Smuts 1995). This work placed Smuts with Sarah Blaffer Hrdy, Jane Lancaster, and others as a key figure in “Darwinian feminism,” a paradigm shift in biology that increased the attention to females as active players in the evolution of human and animal societies.

Smuts’ research has covered a wide range of topics relevant to the development, maintenance, and function of long-term social relationships. This has included studies of chimpanzee social relationships (Baker and Smuts 1994; Wrangham and Smuts 1980), infant development and mother-

infant interactions in wild bottlenose dolphins (Mann and Smuts 1998, 1999; Smolker et al. 1993), social play and friendships in dogs (Bauer and Smuts 2007; Smuts 2014; Trisko et al. 2016; Ward et al. 2008), and the evolution of cooperation (Pepper and Smuts 2000). Smuts has also authored more personal work on her experiences with animals as individuals (Smuts 2001, 2006) and has provided commentaries for *Scientific American*, *Discover Magazine*, *Natural History* magazine, *American Scientist*, *The New York Times*, and National Public Radio. She won several prestigious awards, including the Presidential Young Investigator Award from the National Science Foundation, the Distinguished Scientific Award for an Early Career Contribution from the American Psychological Association, and the John Burroughs Association prize for Best Nature Essay of 2001.

Robert Smuts

Robert W. Smuts received his Bachelor of Arts degree in history from Queens College in 1941. He attended Harvard Business School, but his education was interrupted by service in Patton's Third Army in World War II. After the war, Smuts spent 8 years at Columbia University as a lead investigator for the Conservation of Human Resources Project and the National Manpower Council. His influential book, *Women and Work in America*, provided a historical analysis of the changing role of women in the workforce between 1890 and the early 1950s (Smuts 1959). This report documented the factors that led increasing numbers of women to seek work outside the home, the obstacles they met there, and the shifts in societal attitudes about women's role in the economy. In a related paper, Smuts used the historical context of this research to question the government's labor force statistics, which, owing to changes in how women's labor was documented, painted a rosier picture of increases in female workforce participation than was warranted (Smuts 1960). These works were notable because, in providing objective documentation of changing women's economic roles, they

also highlighted the large disparities still present in opportunities, conditions, and compensation. In a similar vein, Smuts wrote about the underutilization of African Americans in the workforce, arguing that segregation and discrimination remained significant obstacles for educational and employment opportunities (Smuts 1957).

Smuts left Columbia University to work in public relations at Ford Motor Company, where he wrote speeches for Henry Ford II and other top executives. After retirement, Smuts took graduate courses and engaged in seminars in evolution and behavior led by a cadre of eminent evolutionary biologists, including G.C. Williams, W.D. Hamilton, Peter Grant, and Richard Alexander. These experiences cemented an early interest, shared with his daughter, in the role of biological factors in human behavior and historical cultural change. From this perspective, he wrote on cultural shifts in body image for women, noting that while fatness was once a valued indicator of health, fertility, and resource access, modern Western societies value thinness (Smuts 1992b). Drawing on his earlier work, Smuts attributes this change to increased women's economic participation, arguing that, in an environment where starvation is no longer a significant threat, women use thinness as a signal of status and a means to compete with each other and with men. This paper elaborates a theme of Smuts' writing in evolutionary psychology, that behavior is highly responsive to context, such that evolutionarily novel conditions may drive new and unexpected strategies. His argument has been interpreted as a critique of the adaptationist program in evolutionary psychology (Tooby and Cosmides 1990), which has emphasized the importance of past environments for shaping current psychological adaptation. The conceptual debate is exemplified in Smuts' engagement with David Buss' work on commonalities in mate preferences across cultures (Buss 1989; Smuts 1989, 1991a, b).

Conclusion

Barbara and Robert Smuts, together and independently, have produced foundational,

multidisciplinary works on the evolution of social interactions and the processes of cultural change that comprise essential knowledge for scholars in evolutionary psychology and anthropology.

Bargaining Model of Suicidal Behavior

Kristen Syme

Washington State University, Vancouver, WA,
USA

Synonyms

Costly apology model of suicidal behavior; Costly signaling model of suicidal behavior

Definition

The bargaining model of suicidal behavior frames such acts as costly signals of need. The following conditions are necessary for the model to operate: (1) the victim encounters of a fitness threat in the environment prior to suicidal behavior; (2) there is a conflict of interest between the victim and invested social partners such that the social partners are not otherwise willing to provide support based on less costly signals alone (e.g., verbal communication); (3) the victim is otherwise powerless to remove the fitness threat on her own; (4) more often than not the victim survives the attempt; (5) the nonlethal suicide attempt communicates to social partners that she is truly in need; (6) the social partners assist the victim in removing the fitness threat.

Introduction

Suicide is a universal human tragedy. According to the World Health Organization, suicide is the sources of more deaths than all wars and homicides combined (Lozano et al. 2013). In light of evolution, we know that all behaviors are either the functional output of psychological mechanisms, by-products of mechanisms that evolved for other reasons, or the product of dysfunctioning mechanisms, and suicidal behaviors (SB) are no exception. Mental health professionals and investigators tend to reasonably assume that SB is a

consequence of one or more dysfunctions. However, theoretically and empirically, evolutionary scientists know that increasing fitness can come at the expense of survival such exhibited in the cases of semelparity or intrasexual combat. Considering the universality of suicidal behavior, some evolutionary researchers have investigated suicidal behavior in an evolutionary light. One popular model called the inclusive fitness model proposes that suicide death could have evolved to benefit genetic kin when the victim (1) has low reproductive potential and (2) is a burden on genetic relatives (e.g., de Catanzaro 1984). The inclusive fitness model concerns suicide death. However, humans have evolved physiological and psychological traits to prevent harm such as pain receptors and conditioned avoidance that are difficult to overcome. In fact, in the USA, most suicidal behavior is nonlethal (Syme et al. 2016). The bargaining model of suicidal behavior (BRM) concerns the evolved function of nonlethal suicide completions.

The BRM, formally developed by biological anthropologist Edward Hagen and tested by Syme et al. 2016, frames self-inflicted harm with intent to die as a costly signal of need. The following conditions are necessary for the model to operate: (1) the victim encounters of a fitness threat in the environment prior to suicidal behavior; (2) there is a conflict of interest between the victim and invested social partners such that the social partners are not otherwise willing to provide support based on less costly signals alone (e.g., verbal communication); (3) the victim is otherwise powerless to remove the fitness threat on her own; (4) more often than not the victim survives the attempt; (5) the nonlethal suicide attempt communicates to social partners that she is truly in need; (6) the social partners assist the victim in removing the fitness threat.

Conflicts of Interest, Costly Signaling, and Suicidal Behavior

Zahavi observed that human speech is a cheap form of communication that is unreliable when there is a conflict of interest between two parties

and therefore an incentive for one to deceive (Zahavi 1993). Taking this view, the BRM suggests that we should predict suicidal behavior to place when there are high stakes conflicts of interest where parties cannot believe each other based on verbal communication alone.

Powerlessness, Fitness Threats, and Suicidal Behavior

According to the BRM, suicide attempts should outnumber suicide completions, and suicide attempts should be more common among those with high reproductive potential whose fitness is constrained but who are otherwise healthy. According to data from the Center for Disease Control, the rate of suicide attempts in young adults exceeds the rate of completions by factors of 10–100 or more, and this ratio diminishes with age (Syme et al. 2016).

In this framework, suicidal behavior is a last resort of the powerless. Farberow and Shneidman (1961) described suicide as a “cry for help.” Psychiatrist Erwin Stengel reported that suicide attempts often occurred in response to an intolerable social or emotional situation and were often nonlethal. Suicidal behavior is thus a plea entailing a gamble with death (e.g., Stengel 1956). The BRM pinpoints severe, fitness threats, such as physical or sexual abuse, as precursors that make this gamble with death worthwhile from the standpoint of natural selection. According to a WHO study, trauma exposure predicts subsequent suicidal ideation and attempts in a dose-dependent sequence (Stein et al. 2010).

Cross-Cultural Research on Suicidal Behavior

Ethnographic data from a range of unique cultures unambiguously demonstrates that SB can effectively communicate dissent and serve as a check on abuse and exploitation, and the BRM frames these protest themes of suicidality in game theoretic terms. For instance, Firth characterized acts

of SB among the Tikopia as a form of protest, particularly for sons in conflict with domineering fathers (Firth 1936). In the Middle East, SB among women is often regarded as recourse against oppressive kin or restrictive social structures (e.g., Billaud 2012), and the anthropological literature abounds with comparable models (see Syme et al. 2016 for review).

Syme et al. (2016) tested the BRM and the inclusive fitness model against 53 distinct cultures from the probability sample of the Human Relations Area Files. In support of the BRM, most victims of SB were powerless (e.g., had little social influence), were in conflict with powerful social partners who were otherwise invested in them (e.g., parents, community leaders), had experienced some type of fitness threat (e.g., rape, physical abuse), and, if they survived, social partners often helped to remove the fitness threat (e.g., put a stop to an arranged marriage). There was comparatively weaker evidence for the inclusive fitness model, which possibly characterized a small fraction of cases in northern latitudes where the environment is harsh, and where the support of noncontributing community members can present a burden. However, these suicides often required the assistance of another, which presents a problem to the theory that suicide for the sake of inclusive fitness is an evolved mechanism.

Conclusion

The BRM conceptualizes SB as a means of communication. In the model’s framework, the functional goal of at least some SB is to credibly signal a desperate need for social support, while death is a by-product of the signal’s high cost. There are several lines of evidence that support this hypothesis. If the BRM is operating, then the function of SB is to obtain protection, and unrelenting abuse would trigger future SB. The cost of the signal, which in this case manifests in self-harm, guarantees to observers that the signal is honest, i.e., the victim of SB is experiencing a severe social threat for which she needs social aid.

Definition

Social status and social behavior can alter the function of the nervous system within crayfish. This research details the experiments that show that dominant and subordinate crayfish can express different serotonin receptors in the nervous system as well as modulate the sensitivity of those receptors expressed.

Introduction

Neuroethology is the study of the neural basis of behavior, and one of the assumptions of the field includes a concept that behavior arises from the underlying neural architecture of the organism's central nervous system. Several studies have supported the concept that changes in the nervous system, either during development or via changes in neurotransmitter function, as a result of experiences, alters the types of behaviors demonstrated by the organism. For many years, this concept was considered a one-way process whereby the neurobiology influenced behavior. However, the classic studies by Don Edwards and his lab showed that behavior can alter not only the neural architecture but also the neural functioning. Specifically, the social system, including the suite of behaviors and the neurobiology of those behaviors, of the crayfish served as evidence that demonstrated that the social status of an individual (dominant or subordinate) can subsequently alter the modulation of behavior by the neurotransmitter serotonin. In addition, the release and modulation of serotonin can then alter nervous system structure, which influences the types of behavior being exhibited by crayfish with either a dominant or subordinate status. This work opened a new approach to neuroethology in that both the behavior and the nervous system of an animal are now considered plastic and flexibly adaptable to social and environmental influences.

Background on Social Behavior

Sociality carries with it several ambiguous ideas, and the degree to which an organism displays

sociality is different across the animal kingdom. Social systems vary from highly organized and (potentially) genetically related organisms that exhibit cooperation (i.e., the social systems in eusocial insects, some species of birds, and primate communities) to the other end of the scale where organisms exhibit aggressive interactions during brief periods of the year, such as mating periods. Crayfish are a model system for studying social dynamics in general and, specifically, the neuroethology of social behavior. Crayfish exhibit agonistic behavior in the laboratory and in the field (Moore 2007). Within laboratory settings, social dominance and hierarchy formation are quite common (Goessmann et al. 2000; Gherardi and Daniels 2003). Thus, crayfish are organisms that display social behavior and can serve as a neural and behavioral model for the development of social hierarchies (Herberholz et al. 2003).

The first observations of social behavior and agonism in crayfish were based off of the obvious visual displays and the use of the large weaponry (claws) (Bovbjerg 1953). Since Bovbjerg's initial observations, the agonistic behavior of crayfish under different conditions has been well established (see below). This large body of work has shown that the interaction of two crayfish leads to agonistic contests that progressively escalate until one of the opponents withdraws (Bovbjerg 1956). Through these interactions, a dominance relationship is formed. For crayfish, a dominance relationship is one in which subsequent social interactions between these pairs is highly predictable (Daws et al. 2002).

The formation of a dominant and subordinate relationship has consequences for time and energy budgets as well as the acquisition of resources. Indeed, the alterations in behaviors exhibited by dominant and subordinate animals formed the basis for the neurological studies of the Edwards lab (more on this later). Subordinate animals rarely seek to engage a dominant opponent and often retreat when approached by a dominant individual (Daws et al. 2002). Dominant animals can actively seek out subordinate crayfish to reinforce their status through short, low-intensity interactions. Although, it must be noted that most of these descriptions of behaviors are from

laboratory studies often in confined aquaria. The social behavior demonstrated by crayfish in the field tends to be of shorter duration and lower intensity than those behaviors found in the lab (Bergman and Moore 2003). The continued reinforcement of status can not only have long-term effects on subsequent behavior but also on sculpting the nervous system of both the dominant and subordinate animals. To understand the role of neuromodulators, like serotonin, and how alterations in nervous system function can produce differing behaviors, the basic dynamics of crayfish agonistic interactions needs to be explained.

Crayfish agonistic interactions are highly ritualized meaning that a set of displays, sensory signals, and behaviors are consistently seen across different species of crayfish and different environmental conditions (Moore 2007). As with many decapods, when two crayfish are placed within a confined area, they will eventually engage in an agonistic interaction. The interaction begins with an approach behavior where the crayfish extend their chelae (claws) in a lateral fashion. Sometimes, the crayfish will modulate the height of their body, which is thought to be a threatening display. These two behaviors usually occur when the crayfish are separated by one to two body lengths of space. The next stage in a contest occurs when the crayfish open their chelae and actively push the opponent around the tank. What is interesting about this stage of the fight is that neither animal closes the chelae to use as a weapon. This has been termed "boxing" because the crayfish appear to be trying to move the opponent around the fighting arena rather than inflict serious harm. If neither crayfish retreats, the level of aggression usually increases such that the chelae are used to grab the opponent in an attempt to flip them over. The final stage escalates when the crayfish appear to try to injure their opponent by grasping with the chelae and ripping at different body parts. While infrequent, some interactions may result in injuries, lost limbs, or even death.

Agonistic interactions are terminated and a dominant or subordinate relationship is formed when one of the crayfish retreats from the fight. Retreating can take one of two different forms. First, the losing crayfish simply backs away and

fails to engage in further fights. The second method, known as a tailflip, is far more rapid. During a tailflip, the losing crayfish rapidly contracts the muscles on the lower part of the abdomen which causes the telson to curl under the crayfish quickly. This motion launches the crayfish backwards and off of the substrate in a rapid retreat fashion. [As a side note, there are actually multiple styles of tailflips each with their own different underlying neural mechanisms (Herberholz et al. 2001)]. The decision to retreat, either by tailflip or a slow retreat, determines the winner and loser of the fight and establishes the roles of dominant and subordinate crayfish. Thus, the neural mechanisms that influence the control of this retreat were the basis of the series of studies performed in the Edwards lab. Before those experiments are described, the different behavioral and environmental influences on social status will be outlined.

The Behavioral and Environmental Influences on Social Status

Dominance and levels of aggression in crayfish are influenced by several different factors that can be categorized as either extrinsic (environmental and sensory influences) or intrinsic (physical or physiological) to the crayfish (Moore 2007). Extrinsic factors include the presence of resources (shelters and food) and sensory signals (visual, chemical, and mechanical signals). Crayfish that have "ownership" over a resource like a territory, shelter, or food source are more likely to defeat and become dominant over intruding crayfish (Graham and Herberholz 2009). Unfortunately, the direct role of different sensory signals on dominant and subordinate status is still unknown, but chemical signals seem to be an important aspect of crayfish social interactions.

The role of intrinsic factors has received the bulk of the social status work in crayfish. The most obvious intrinsic factor that influences dominance is size of the animal or size of the chelae. Larger animals with larger weaponry are dominant over smaller animals (Pavey and Fielder 1996). The sex of the crayfish also influences dominance status as size-matched males tend to be dominant over females (Wofford et al. 2015).

Reproductive status can also serve as a varying intrinsic quality that dictates dominance. Within many crayfish species, both the male and female cycle between a reproductive and non-reproductive state. Reproductive crayfish are dominant over nonreproductive crayfish (Figler et al. 1995). Previous social history and neurochemistry are critical factors in the dominant status of crayfish. As in many species, crayfish exhibit what is known as winner or loser effects (Daws et al. 2002). Crayfish with a previous social history of winning are more likely to remain dominant and win their next set of agonistic encounters. In an opposite fashion, crayfish that have recently lost encounters are more likely to continue to lose subsequent contests and become or remain subordinate. The winner and loser effects within crayfish are reversible signaling that any underlying neural changes that are associated with dominant and subordinate behavior must also be plastic. Since the retreat, by tailflip, determines the outcome of agonistic interactions, the Edwards group (Shih-Rung Yeh and Don Edwards with others) focused their neurological work on the flexibility and modulation of the tailflip circuitry in the crayfish. The ability to artificially manipulate dominant status through winner and loser effects gave them the experimental model which would directly connect social status and neurobiology.

The Underlying Neurobiology of Social Status

With the advent of modern techniques in neurobiology, several groups began working on the neural circuitry of dominant and subordinate behavior, with particular attention being paid to the neurons involved in a retreat response (tailflip) and the role of serotonin in dominant and subordinate animals (Edwards and Kravitz 1997). The tailflip circuitry of the crayfish has been a favored neurobiological prep since the pioneering work of Wiersma (1947). Since that initial work, the neurons involved in the tailflip response as well as the neuromodulation of that response have become fairly well known. Crayfish can exhibit three different types of tailflips, classified by the neural control necessary to perform the behavior (Krasne et al. 2014). The details of these three responses

and their role in the ecology of the crayfish are beyond the scope of this entry, but the critical feature of these tailflips is the identified neurons that control each of their activations. Each of the tailflips are controlled by two giant command neurons: the medial giants and the lateral giants. The command neurons are found in bilateral pairs along the dorsal position of the ventral nerve cord of the crayfish. Within invertebrate systems, the diameter of the neuron determines conduction velocity. Thus, both giant neurons (up to 80 μm in diameter) have a high speed of conduction which evokes rapid tailflips. Both neurons activate structures called motor giants and fast flexor motor neurons which further explain the rapid response of the crayfish tailflip. Finally, these neurons are termed command neurons because they control the entire sequence of activation of the tailflip from neuron to behavioral output. Modulation of the sensitivity of these neurons can also modulate the speed and sensitivity of activation of the tailflip (Krasne 1969; Krasne and Edwards 2002). This modulation introduces the possibility that social behavior and dominance (as determined by which animal does not retreat) may be explained by the sensitivity of the neurons controlling the tailflip response. This hypothesis, coupled with the presence of winner and loser effects, is what the experimental work by the Edwards lab tested with their classic study (Yeh et al. 1996, 1997).

The details of their experiments are elegantly simple (Yeh et al. 1996, 1997). They first placed two socially naïve crayfish in an aquarium and waited until a dominant and subordinate relationship had firmly been established. After this relationship was established, both crayfish were dissected and the lateral giant neurons were tested for their sensitivity to serotonin. Using electrophysiological techniques, the researchers applied different concentrations of serotonin to the bath surrounding the dissected neurons from subordinate, dominant, and control (i.e., socially naïve) animals. During application, they measured the excitatory postsynaptic potential of the lateral giants to test their excitability to different concentrations of serotonin. The results showed that serotonin had the ability to modulate the

excitability of the lateral giant neurons, meaning that serotonin sets the gain of the neurons. The exact effect of serotonin on modulating this response depended upon the social status of the crayfish. In dominant animals, serotonin increased the sensitivity of the lateral giants which increased the probability of firing and the opposite effect was seen with the subordinate animals. Thus, a first set of conclusions that can be drawn from this work is that the modulation of social neural networks by serotonin is dependent upon the social history of the crayfish.

However, this initial result was counterintuitive. If dominant animals are more sensitive to serotonin and their lateral giants are more likely to fire, why does this lead to dominance? The researchers used a set of different compounds on the dissected neurons in an attempt to understand the exact physiological mechanism of change that is occurring at the neural level. They found that different classes of serotonin receptors were being expressed in the dominant and subordinate animals. One class of serotonin receptors increases the excitability of the lateral giant neurons and a second class of receptors reduces the excitability of the lateral giants. Dominant crayfish expressed more of the first class of receptors (excitability) and the subordinate animals expressed more the second class of receptors (less excitable). Work in another lab (Ed Kravitz from Harvard) has shown that the lateral giant neuron is also involved in activating other neurons that release serotonin in other areas of the crayfish nervous system (Kravitz 2000). These other areas are involved in modulating levels of aggression in crayfish. Thus, an increase in excitability of the lateral giant, which is mediated by the expression of certain receptors, also increase the level of aggression in crayfish by activating a global release of serotonin. Thus, a second conclusion from this work is that changes in social status can change which serotonin receptors are expressed within crayfish, which in turn affects sensitivity to circulating serotonin.

These changes in sensitivity to serotonin are not permanent and are reversible. In a continuation of their experimental design, the Edwards group placed two subordinate crayfish within a

tank and waited for one of the previously subordinate animals to become dominant. Again, the lateral giant neurons were dissected from the animal and placed in a petri dish to measure their responsiveness to serotonin. The responses of the lateral giant were reversed and instead of the activation being suppressed by serotonin, the responses were enhanced. The neurons now responded as if they came from a dominant crayfish. This change in firing sensitivity took around 2 weeks to occur. In a final test of their findings, the researchers paired two dominant crayfish in a tank to test whether dominant crayfish altered their neurophysiology in a similar fashion to the subordinate animals. Surprisingly, the dominant crayfish exhibited much higher levels of aggression and their fights ended in death at a far higher rate than other fight conditions. After one of the crayfish eventually exhibited subordinate behaviors, Yeh and Edwards tested their lateral giants for serotonin sensitivity. Unlike the change in physiology found in the paired subordinate fights, the “losing” dominant crayfish still exhibited the enhanced sensitivity to serotonin. Yeh and Edwards demonstrated that dominant animals may exhibit subordinate behavior, but their nervous system still exhibited the dominant physiology for long periods after losing their dominant status. Although social status can change a nervous system's sensitivity to serotonin, both the initial change and any subsequent change in physiology is dependent upon the social status of the crayfish. Subordinate crayfish exhibit loser effects due to a decreased sensitivity to serotonin, but this change in neural sensitivity is reversible on a short time scale. Conversely, dominant crayfish exhibit enhanced sensitivity to serotonin and this change in enhanced sensitivity is a long-lasting change, exhibiting the possibility that winner effects are more potent than loser effects in crayfish.

Conclusion

The results from this study demonstrated three essential points for the plasticity of the nervous system. First, behavior, in general, and social

status, specifically, alters the functional properties of the nervous system of the crayfish. From a neuroethological point of view, behavioral experiences alter nervous system function. Second, this change in nervous system function can vary depending upon the prior experience. Serotonin functionality in crayfish enhanced excitation of escape neurons in dominant animals and suppression excitation in subordinate animals. Third, the temporal properties of this change are also dependent upon the behavioral experience. Changes in serotonin sensitivity were longer lasting in dominant animals than subordinate animals. Taken together, these results have clearly demonstrated a more plastic or flexible nature of the nervous system that is highly dependent on the type and intensity of behavioral experiences.

Minimal obligatory parental investment; Sex difference in reproductive success variance

Definition

Bateman's Principle states that there is greater variance in the reproductive success of males compared to females, which has implications for mating and relationship psychology in humans.

Introduction/History

In the late 1940s, English geneticist and botanist Angus John Bateman published a seminal work

detailing what would later be called Bateman's Principle: the notion that compared to females, males in most species exhibit greater reproductive success variance. That is, males tend to differ more in reproductive success than females do (Bateman 1948). Bateman's intention was to corroborate and refine Darwin's sexual selection theory despite his unrelated botanic research interests. Previous evidence had suggested that, in virtually all species studied, males were willing and eager to pair and copulate with any female, while females were more discriminatory when selecting male mates. This asymmetry was thought to be responsible for the greater intra-sexual competition observed among males compared to females (Tan 1946). Darwin (1871) had previously argued that the mating system of a particular species was the primary cause of these sex differences in discrimination and competition, and that intramale selection (i.e., competition among males to be the mate choice of one or more females) was most prominent because it was engendered by the most common mating systems, monogamy with more males than females and polygyny. However, according to Bateman this reasoning was flawed, and Darwin had it backward. If the mating system determined sex differences in discrimination and competition, why would monogamy with more males than females and polygyny be exponentially more common than other mating systems? The overwhelming prevalence of these mating systems instead led Bateman to believe that intramale selection *caused* the emergence of particular mating systems. As Bateman succinctly put it, "It is thus desirable to search for a fundamental cause of intra-masculine selection, independent of mating system and probably inherent in the mechanics of sexual reproduction" (1948, p. 352).

Accordingly, Bateman set out to illuminate the mechanics of sexual reproduction he thought might be responsible for intramale selection. Studying fruit flies (*Drosophila melanogaster*), he found evidence that male fruit flies' reproductive success was dependent on the number of partners they were exposed to and copulated with, while female fruit flies' reproductive success was not dependent on this factor. Bateman

reasoned that these findings were ultimately caused by differences in fertility limitations between males and females. Males, on the one hand, produce an overabundance of sperm that theoretically could beget an extremely high number of offspring, far more than most males have ever or will ever produce. This led him to conclude that males' reproductive success is not limited by their gamete production. Females' reproductive success, on the other hand, is limited by their gamete production as females produce only a limited number of eggs in their lifetimes. Moreover, females exert substantially more energy nurturing their eggs than males do nurturing their sperm, suggesting that females act as the "limiting factor" in reproduction.

Overall, Bateman found solid evidence for his theory that mechanical reproductive differences between males and females give rise to intramale selection. Because males are not limited by their gamete production, while women are, males are more eager to mate with any and multiple females, while females are more selective when choosing a mate. It derives that high-quality males are able to mate with a large number of females while low-quality males are not. Females, on the other hand, should have relatively fewer problems finding a mate. In a nutshell, the reproductive success of males is more variable than the reproductive success of females.

Evidence in Humans

As theorized by Bateman (1948) and later expanded upon by Trivers (1972), evidence for sex differences in reproductive success variance (Bateman's Principle) in humans is overwhelming. While comparing data across vastly different societies, Betzig (2012) found strong evidence that males exhibited greater variability in reproductive success (in this case, number of children conceived) compared to females. Further, she found that this effect was moderated by the subsistence of the society in question: the variance of reproductive success was similar for both men and women in hunter-gatherer societies (low subsistence), while the variance of reproductive success

was substantially higher for men than for women in full-time agriculturalist societies (high subsistence). The author reasoned that this moderation effect occurs because as subsistence intensifies, the size and available resources of societies increase, which causes more pronounced hierarchical societal structures.

Indirect evidence for Bateman's Principle also emerged from evolutionary psychology research. For example, evidence strongly suggests that men evolved to be more aggressive, violent, and competitive than women in order to successfully partake in intense intrasex competitions for females (Daly and Wilson 1994). In their study, Buss and Dedden (1990) reported that men, compared to women, were much more likely to physically assault other men when competing for women, while women, compared to men, were much more likely to use non-violent means (e.g., verbal aggression) when competing for men. Evidence also suggests that women are choosier when selecting mates compared to men. For instance, Clark and Hatfield (1989) found that women, compared to men, had a much higher threshold for accepting an invitation to go on a date or have sex with an attractive stranger of the opposite sex. When men were invited to engage in sex by a female stranger, three-quarters of them accepted, but when women were invited to engage in sex by a male stranger, none of them accepted. Lastly, evidence clearly suggests that men are more promiscuous and interested in short-term relationships than women (Simpson and Gangestad 1991). Lippa (2009) compared data on sociosexuality (i.e., one's endorsement of and willingness to engage in noncommitted sex) in 53 nations ($N > 200,000$) and found that in every single nation, men reported higher sociosexuality than women (average $d = 0.74$).

Other Factors

Despite the overwhelming evidence in favor of Bateman's Principle in humans, other factors influence reproductive success and mating psychology in humans. For example, sex-ratios (i.e., the ratio of males to females in a society) affect the

reproductive success and strategies of the average individual in a given society (Moss and Maner 2015). Men in societies where women outnumber men have greater marriage and reproductive success compared to societies where men outnumber women (Pollet and Nettle 2007). Societal rules, laws, and customs, which can prohibit or discourage polygamy, also have an effect on the average individual's reproductive success.

Conclusion

To summarize, Bateman's Principle is the phenomenon by which males have a greater variance in their reproductive success than females. While this phenomenon had been identified in many species before Bateman's theorization, Bateman was the first to propose that the proximate cause of this difference laid in the sexual reproduction mechanics that distinguish males and females. Females act as the "limiting factor" in reproduction due to the limited number of gametes they produce compared to males, who produce gametes in abundance. This sex difference in reproductive success, which applies to many species including humans, has a number of implications: males engage, on average, in more intense and physical competitions for females than females do for males, and males, on average, are less selective when choosing a sexual partner than females.

Definition

Forgiveness mechanisms are designed to solve problems connected to preserving valued relationships in spite of previous damages. To be forgiving is to be able to change the motivation and emotional states towards someone who has harmed us, leaving behind a disposition for revenge with negative states of mind, for overcoming of animosities with positive states of mind.

Introduction

Forgiveness is an inbuilt human nature resource and a standard human social instinct (McCullough 2008). Forgiveness is defined as a prosocial change in relation to a transgressor in spite of his harmful attitudes (McCullough et al. 2000). In general, being forgiving is associated with relational, emotional, and physical well-being (McCullough 2008).

The literature indicates several elements as related to forgiveness, among which are the personality of the individual, specific elements of the individual who has done something wrong, the relationship between the offender and the victim, as well as other socio-cognitive aspects (Billingsley and Losin 2017; McCullough 2008). These combined elements influence the individual to experience forgiveness as a set of motivational changes that has a positive effect. As a result of forgiveness, individuals feel less motivated to take revenge on the aggressor, as well as less

motivated to be displeased with them; these motivational changes are increased by the goodwill of the aggressor (Karremans and Van Lange 2004).

Thus, forgiveness is considered to be an internal process of overcoming animosities and negative emotions, replacing them with positive states, which enable the reparation of the relationship with the aggressor (McCullough 2008). In this context, reconciliation may be understood as one of the more basic consequences of forgiveness, seen as it aids in the maintenance of the social structure (Billingsley and Losin 2017; Strang 2002). By preserving relationships, the benefits of group life are maintained, ensuring survival and development.

Thus, it is necessary to understand how evolution selected forgiveness from its adaptive mechanisms. The evolutionary functions of forgiveness aid in comprehending the context in which this action was selected, how and why. In addition, there are ways to perceive different types of forgiveness in each culture. This way, to identify forgiving individuals it is also necessary to understand the factors that enable human beings to forgive.

Evolutionary Functions of Forgiveness

According to McCullough (2008), in his book “Beyond Revenge: The Evolution of the Forgiveness Instinct,” there are two functions over which the ability to forgive was naturally selected. The first refers to the ability to help ancestral humans to live well with their genetic relatives; the second refers to the ability to help ancestral humans establish and maintain cooperative relationships with nonrelatives. However, it is important to point out that the human ability to forgive only exists under specific circumstances.

Initially, it is understood that severe retaliations and revenges against genetic relatives, such as killing brothers, sisters, and children, decreased inclusive fitness. So, the function of forgiveness to promote good coexistence with relatives was probably selected as a solution to some problems, such as avoiding that genes be decimated by reducing the relatives’ aptitude. Thus, forgiveness

allowed that alliances between groups were developed and maintained.

The second function of forgiveness may have evolved from the need of cooperation between nonrelatives. In the Prisoner’s dilemma (Axelrod 1997), one of the more efficient strategies is Tit-for-tat, a primordially cooperative strategy, but that retaliates and forgives. Being forgiving in this situation may be beneficial because, if, after deserting, your partner starts cooperating again, you instantly cooperate with him, showing you are willing to be in an alliance again. Cooperation results in higher payoffs than desertion. The studies about strategies that followed found that a few unexpected situations happened in cooperation and other strategies became more adaptive; however, detailing them is not important at the moment. In any case, the common ground is that organisms that survived the selective process had forgiveness as an adaptive skill.

Thus, forgiveness was selected with the function of developing and maintaining alliances between relatives and nonrelatives, motivating them to return to cooperation by restoring the relationship that may have been broken by some desertion or conflict. Forgiveness may have evolved to help organisms in promoting and adapting their genetic relatives and in cooperating with nonrelatives. Therefore, the main adaptive function of forgiveness seems to be to help individuals preserve their valuable relationships (McCullough et al. 1997). However, even though humans have developed mechanisms to forgive, being forgiving is more likely to happen among cooperative partners, that is, to members of the small groups of people closest to them. In fact, forgiveness helps preserve the relationships that are most valuable, from family, partners, and close friends where there is the key element of trust (Kurzban 2003, McCullough 2008).

Be Forgiving

Nonhuman animals, such as chimpanzees, often engage in friendly behavior such as kissing, touching, and hugging after aggressive conflicts (de Waal and van Roosmalen 1979). Although reconciliation and forgiveness are not exactly the

same thing, the greatest goal of forgiveness and its greatest effect is reconciliation (Karremans and Van Lange 2004). However, forgiveness is a conditional adaptation; despite having the capacity, forgiveness will only happen under certain circumstances (McCullough 2008). Thus, there are three main conditions that activate forgiveness, which will be briefly exposed below.

The first is careworthiness: to be forgiving of transgressors who are seen as appropriate targets for kindness and compassion. Getting involved with others demands physical and psychological energy, so the targets of greater care and forgiveness will be genetic relatives. Forgiveness is based on the same mechanisms that generate care (McCullough et al. 1997, 1998). With regard to forgiveness directed toward individuals not close to us, empathy plays a fundamental role in promoting forgiveness (Batson and Ahmad 2001; Giancola 2003).

The second condition is the expected value of a relationship, where forgiveness is more likely when the victim realizes that the relationship with the offender is valued. In relationships where there is a high expected value before transgression, being forgiving is more likely because the threat of losing a valued relationship motivates finding ways to restore that bond. The prediction of future positive and valuable interactions with the transgressor also influences the willingness to forgive (McCullough 2008).

The third condition to be forgiving is perceived security, that is, people are more inclined to forgive those who are not willing or able to harm again in the future. People are more likely to forgive someone who behaved unintentionally or unconsciously than willful and malicious transgressions (Strang 2002). Therefore, under such circumstances, it is possible to activate the mechanisms of forgiveness, socially identified with some signs such as apologies, gestures, and self-abasing displays and compensative behaviors.

Conclusion

As stated earlier, forgiveness can be defined as a prosocial change of attitude towards someone

who has committed some kind of emotional or physical harm (McCullough 2008). Among the functions attributed to forgiveness is the aid in developing relationships with peers, with or without blood ties, in a cooperative way (de Waal and van Roosmalen 1979). At more complex levels of analysis, forgiveness has allowed the development and maintenance of alliances, especially in situations where one party violates explicit or implicit social norms (Billingsley and Losin 2017).

Thus, forgiving individuals are those who perceive offenders as worthy of care under certain circumstances, for being valuable to the victim. In this way, individuals who seek forgiveness try to awaken these psychological conditions in people, by apologizing, engaging in self-abasing displays, in addition to trying to compensate the victim (McCullough 2008).

Behavioral Economics

Vincent Barnett
London, UK

Definition

Behavioral economics is conventionally defined as economic theory that incorporates insights

from contemporary psychology, cognitive science, cultural theory, human physiology/emotional states, and neuroscience. However, the term “behavioral economics” can be seen as potentially subversive because it can be taken to suggest that the remainder of economics is non-behavioral and – by implication – excessively abstract and therefore partially inaccurate.

Introduction

This entry will first provide an account of the nature and scope of behavioral economics as it was outlined by one of its founding fathers, George Katona. This entry will then go on to discuss the work of four very important more recent behavioral economists – Daniel Kahneman, Amos Tversky, Richard Thaler, and Vernon Smith – in more detail. Following this, in the latter part of the entry, it will consider the consequences of some ideas developed by evolutionary psychologists and biologists for the nature of behavioral understanding in economics more widely conceived. It will accomplish this task by means of case-studies of how two individual concepts from economics, the invisible hand metaphor and the maximization conception of economic rationality, fit (or do not fit) within the framework of analysis provided by evolutionary psychology. Finally, a relatively new subfield of behavioral economics – neuroeconomics – will briefly be considered in relation to its significance for evolutionary psychology.

George Katona

George Katona (1901–1981) was a pioneer in the field of behavioral economics with an early background in Gestalt psychology who was born in Budapest, but who later emigrated to the USA and worked at the Cowles Commission and then the University of Michigan (Katona 1960). He was the author of *Psychological Analysis of Economic Behavior* (Katona 1951) and the inventor in the mid-1940s of the US Index of Consumer

Sentiment (ICS), an innovative empirical measure of consumer expectations.

Katona defined behavioral economics as containing three fields of analysis: empirical studies of the behavior of businesspeople/consumers; analysis of decision-making processes in relation to behaviors like spending, saving, and investing; and the study of economic motives, attitudes, and expectations at a deeper level. He also identified subfields of behavioral economics as follows: the study of consumer/savings/business behavior; how income is spent and augmented; the nature of different market systems and associated behaviors; politico-economic attitudes (e.g., attitudes to taxation, government spending and so on); and workplace behavior/broader organizational behavior (Katona 1980, 3–6).

To examine one topic in more detail, the mainstream economist’s conception of rational behavior, on this topic Katona explained that:

In contrast to the emphasis of [mainstream] economic theory on rationality, defined as weighing available alternatives and choosing the alternative that maximizes utility or profits, behavioral economists found a common occurrence of habitual behavior – doing what has been done in the past, following established routines and following leaders – occasionally interrupted by genuine decision making. Only in those relatively few instances when the decision really matters do strong motivational forces arise that lead businessmen and consumers to proceed in a circumspect manner. Even then the alternatives considered are usually restricted according to their attitudes and expectations, and a satisfying course of action is chosen rather than one that will optimize the outcome. (Katona 1980, 13–14)

This account articulates the significant difference between what were classified by Katona as the unrealistic assumptions of much of mainstream economics, and the more realistic assumptions of his own brand of behavioral economics. Elsewhere, he presented a more detailed account of how he believed human actions and decision-making processes operated, highlighting five ways in which real-world behavior differed significantly from that proposed by utility-maximization-based economics.

Real human behavior reflected the influence of multiple and sometimes competing motives, for

instance with respect to evaluating the sometimes-opposing multiple qualities of goods; real behavior involved a significant degree of group decision-making in addition to individual decision-making, for example, family-based or firm-based decision-making; real behavior involved the prevalence of uncertainty about the future, for example, in relation to spending capacity; real behavior involved ignorance of at least some of the relevant facts, for example, in relation to the scope of a given product's market availability; and finally, real behavior involved a degree of confusion/uncertainty about how decision-making processes should best be undertaken, even if all the relevant facts were available (Katona 1980, 27).

Following on directly from J.M. Keynes's work in the 1930s on the importance of psychological propensities for an understanding of economic behavior (Katona 1942, 17; Barnett 2017), Katona and his brand of behavioral economics was virtually the sole efforts of a lone wolf in the first two decades after World War Two. However, by the end of the twentieth-century, behavioral economics had developed significantly and blossomed into a very important subfield of economics in its own right, partly through the very influential efforts of two key individuals, Daniel Kahneman and Amos Tversky.

Daniel Kahneman and Amos Tversky

Daniel Kahneman (1934–) is well-known for his work on heuristics and biases, loss aversion, prospect theory, framing effects, and choice under uncertainty. He is the co-author of *Judgment under Uncertainty: Heuristics and Biases* (Kahneman and Tversky 1982) and was awarded the Nobel Prize in Economics in 2002 for his work on prospect theory. Amos Tversky (1937–1996) was Kahneman's co-author of the work on prospect theory, and his important contribution to this theory was acknowledged posthumously in the Nobel Prize citation about Kahneman from 2002. Some of Tversky's work on heuristic choice mechanisms has been usefully employed by contemporary evolutionary psychologists (Todd and Gigerenzer 2007, 206).

In their work on heuristics and biases, Kahneman and Tversky argued that individual decisions are often made using a limited number of heuristic principles that simplify the decision-making process, but which can lead to either moderate or severe errors in certain situations. They have also identified various specific biases that people can be subject to, such as the representativeness heuristic, the conjunction effect, base-rate neglect, and the law of small numbers. In the latter case, Kahneman and Tversky's research suggested that individuals tended to exaggerate how often a small sample accurately resembled the wider population from which it was drawn.

In their work on prospect theory, Kahneman and Tversky maintained that the real carriers of value to human individuals were relative changes in wealth and welfare, rather than final or absolute states. For example, the same degree of wealth could connote extreme poverty for one person and great wealth for another, depending on the particular context of their lives. The billionaire whose total wealth was suddenly reduced to only \$10,000 would feel like they had been greatly impoverished, whereas if a rich benefactor gave a homeless individual with no possessions at all \$10,000 as a gift, then they would feel almost like a millionaire.

Following on from this, Kahneman and Tversky maintained that people are generally loss-averse, i.e., they value an equivalent loss higher than an equivalent gain. People also exhibit diminishing sensitivity to ongoing gains made of the same extent as they accumulate and are subject to the framing effect or to precisely how a particular issue is formulated. Differently framed formulations of the same question can sometimes result in very different answers. For example, patients can respond differently when it is recommended that they have surgery with a 70% survival rate, compared to the same surgery when it is recommended with a 30% chance of death.

Kahneman and Tversky not only frequently collaborated with themselves in their behavioral economics innovations but sometimes with other individuals as well. One very significant such individual was Richard Thaler with respect to collaborative work on the endowment effect

(Kahneman et al. 1991). The endowment effect is the hypothesis that people ascribe greater value to an item merely because they currently own it, as compared to what their valuation of the same item would be if they did not own it or if someone else owned it.

Richard Thaler

Richard Thaler (1945–) is well-known for his work on the consequences of the limitations of rationality, the nature of social preferences, and a lack of self-control for how economic decisions are made, and how they affect market outcomes. He is the co-author of *Nudge: Improving Decisions about Health, Wealth, and Happiness* (Thaler and Sunstein 2008) and the author of *Quasi Rational Economics* (Thaler 1994). He was awarded the Nobel Prize in Economics in 2017 for his work on bridging the gap between the economic and the psychological analyses of decision-making.

Thaler's co-authored book *Nudge* analyses how groups and organizations can assist individuals in making superior choices in their daily lives from a perspective of libertarian paternalism. Thaler and Sunstein divided human thinking/thought processes into two types: automatic/instinctive versus reflective/self-conscious. According to Thaler and Sunstein, in part because of differences/conflicts between the two types of thinking, individuals can be subject to various biases, fallacies, and heuristic frameworks, which may in certain situations lead to them making bad decisions and/or mistaken judgments.

The various heuristic frameworks and/or biases outlined by Thaler and Sunstein include: anchoring, or relying too much on one trait or one piece of information when making judgments, rather than using a wide range of information; availability, or using an example very easily brought to mind rather than a more relevant example that is more difficult to locate; status quo bias, or blindly continuing an existing behavior without further contemplation; and the herd mentality, or being too influenced by other people and/or existing trends.

From the perspective of evolutionary psychology, it could reasonably be hypothesized that some of these biases and heuristic frameworks are psychological mechanisms/instincts that have evolved by natural selection to provide human beings with a “fast and frugal” means of making decisions in situations in which speed of decision-making is a crucial factor at play (Todd and Gigerenzer 2007, 197). However in other situations, when speed is not so crucial, using these same instincts/biases, without additional reflective/self-conscious thought, might result in mistaken judgments and decisions being made.

Vernon Smith

Vernon Smith (1927–) is an experimental economist who was awarded the Nobel Prize in Economics in 2002, and who is known also for his work on understanding the nature of behavioral rationality. As Smith himself explained, “experimental market economics and behavioral economics are complementary” (Smith 2008a, 155).

Rationality is usually defined by mainstream economists as some type of maximization behavior in pursuit of self-interest. Methodological individualism underlies this approach, where each human being is regarded as a separate, self-contained unit of decision-making and action. However, a fundamental principle of evolutionary biology – inclusive fitness – challenges this approach, as genetic relatedness means that individuals are embedded in kinship groups (Barnett 2015, 653). In fact from a gene's-eye perspective, there are no such things as individuals, as genetic code is shared among family members.

Smith's definition of constructivist rationality widens the framework of operation of maximization-type rationality by applying it to individuals and to organizations. Its function is explicitly limited to the *conscious* analysis of superior alternative feasible pathways and it refers to optimal design in the incentive structure (Smith 2008b, 138). However, Smith is aware that this constructivist rationality is not comprehensive and requires augmentation by a different type of

rationality that takes account of the non-conscious aspects of behavior.

He defined his own version of ecological rationality in expansive terms as follows. An ecologically rational order was:

an undesigned ecological system that emerges out of cultural and biological evolutionary processes: homegrown principles of action, norms, traditions and “morality.” Ecological rationality uses reason – rational reconstruction – to examine the behavior of individuals based on their experience and folk knowledge, who are “naïve” in their ability to apply constructivist tools to the decisions they make; to understand the emergent order in human cultures; to discover the possible intelligence embodied in the rules, norms, and institutions of our cultural and biological heritage that are created from human interactions but not by deliberate human design. People follow rules without being able to articulate them, but they can be discovered. (Smith 2003, 469–70)

Smith was careful to explain the relation between his two types of rationality. Constructivist rationality accepted current economic structures (e.g., particular market auction systems) as given and attempted to formally model these structures using explicit rules of behavior and operation. Ecological rationality in contrast asked: how did these structures come into being (Smith 2003, 471)?

For evolutionary psychologists, however, ecological rationality has facilitated adaptive problem-solving in relation to the contexts that the human mind encountered during its long-period of evolution. As has been explained about environmentally specific statistical regularities:

... heuristics that use just a little of the patterned [environmental] information and process it in simple ways can make decisions that are fast, accurate, and adaptive ... Adaptive behavior emerges just when the mechanisms of the mind are properly matched to the (information) structure of the environment – producing what we call *ecological rationality*. (Todd and Gigerenzer 2007, 199)

As all ecologically rational cognitive processes relate to specific, concrete problems, they are context-dependent/path-dependent rather than general in nature (Egidi and Rizzello 2006, 675).

While Smith was confident that both of his types of rationality had relevance to understanding how

markets operated, evolutionary psychologists see their conception of ecological rationality as being in conflict with the standard account of rationality provided by most economists. Thus, it has been suggested by some evolutionary psychologists that “we should expect humans and other animals to show ‘ecological rationality’, rather than the economists’ perfect rationality” (Dunbar and Barrett 2007, 128). Contrast this with how economists usually interpret Smith’s work in experimental economics: “People are *more* rational than the agents in our models” (Eckel 2008, 570: emphasis added).

Smith concluded one article with a list of “working hypotheses” that originated from his work on experimental economics. Listed as number five was the idea that rules governing markets as institutions emerge as spontaneous order, through evolutionary processes that have adapted them to requirements:

What emerges is a form of “social mind” that solves complex organizational problems without conscious cognition. This “social mind” is born of the interactions among all individuals through the rules of institutions that have to date survived cultural selection processes. (Smith 2003, 500)

In the final section of this entry, it will be suggested that the idea of the emergence of a “social mind” is potentially equivalent to the hidden hand metaphor common in economics, and also to a well-known and long-standing fallacy in evolutionary biology.

The Invisible Hand

The invisible hand is perhaps the most famous metaphor found in all of economics: individuals pursuing their own self-interested behavior invariably end up serving the good of society as a whole. As a metaphor, it is used primarily to lend support to a *laissez faire* approach to economic policy or providing an instinctive argument as to why less governmental or state control and intervention is generally better than more.

The idea of the invisible hand also has what can be called a technical meaning, i.e., if it were possible to calculate the effects of an aggregate of all individuals pursuing unbridled self-interest,

versus this aggregate with additional controls on self-interest that were designed “for the social good,” then the result would necessarily and always be superior in the former case than the latter. It will be demonstrated here that this technical meaning of the invisible hand is false, as it is the equivalent of an argument that was previously made in support of the idea of group selection in evolutionary biology, an argument which is now accepted as erroneous.

This basic parallel has recently been made by Robert Trivers, a leading evolutionary biologist. Trivers wrote that mainstream economists:

... argue that individuals acting for personal utility will tend to benefit the group; they are (thus) often blind to situations where unrestrained pursuit of personal utility leads to disastrous effects on group benefits ... This is a well-known fallacy in biology, with hundreds of examples. Nowhere do we assume in advance that the two kinds of utility are positively aligned ... the result is the equivalent of the group selection fallacy – yes, selection acts on individual utility but magically enough, general utility is thereby generated? (Trivers 2013, 311–312)

As economists are not always well-versed in evolutionary biology, this entry will outline the consequences of Trivers’ parallel between the invisible hand and group selection in more detail, in order to illustrate how behavioral economics needs to take account of the principles of evolutionary biology.

One argument previously advanced in support of group selection is now acknowledged as mistaken, what will be called the “higher good” argument. The “higher good” argument is that evolution by natural selection can sometimes act for the good of the group or the species as a whole, when in fact evolution only ever acts to promote the interests of individual genetic lines. The consequences of natural selection acting on genes for higher-level units such as families, tribes, nations, species, and ecosystems cannot be known a priori, instead the particular circumstance have to be examined before the effects of evolution on higher-level units are known. The meaning of this mistake will be elaborated in what follows.

Consider a group of birds that are divided into two types of foragers, prudent and imprudent foragers, each subgroup initially being of equal size.

The former birds restrain their feeding and reproduction in order to manage their environment for the long-term, while the latter birds eat and reproduce as much as is physically possible (Wilson 2007, 50). If the invisible hand were to operate on this hypothetical group, then it would balance the behaviors of the two subgroups to produce a long-run equilibrium that maintained the environment in a healthy state for both types of foragers to enjoy, by selecting to some degree against the imprudent foragers who naturally reproduce more quickly, so as to maintain the initial position of ecological balance.

However what would happen in the real world would be that, because the imprudent foragers have the higher relative fitness and reproduce more, they would increase their percentage frequency in the group over time. The fact that this would eventually produce a population collapse after the growing number of imprudent birds exhausted their food source is in no way precluded by natural selection, as it never acts “for the good of the group” or the good of the ecosystem.

Another example was provided by Trivers himself. In some types of monkeys, male infanticide of dependent offspring of current mates, who were fathered by other males, was in the past interpreted by biologists as a population-control mechanism designed to serve the good of the group, by ensuring that the total population level was kept in line with the local ecology (Trivers 1985, 74). In fact, this murder simply serves the individual interest of the current male partner by bringing the female into reproductive readiness more quickly and preventing her attention being taken by offspring from previous mates (Trivers 2013, 308). Since a “horrific” example of monkey behavior was being considered (the murder of infants), there was a human desire to believe that a “higher good” would be the outcome (population management), but in fact, nature has no such desire to guarantee the good of the group.

The fact that the “higher good” argument for group selection is erroneous has a twofold parallel with the invisible hand in economics, what can be translated into the rightwing invisible hand fallacy

and the leftwing anti-invisible hand fallacy. If the rightwing invisible hand fallacy is that the “good” invisible hand magically guarantees that individuals pursuing their self-interest will always result in the social good being enhanced, then the leftwing anti-invisible hand fallacy is the opposite that the absence of the invisible hand (or a wicked invisible hand) guarantees that individuals pursuing their self-interest will never result in the social good being enhanced.

The scientific position based on the analogy with natural selection is that sometimes individuals pursuing their self-interest will translate into the social good being enhanced and sometimes it will not do so, it all depends on the specific details of the particular example that is being considered. Although producing a “higher good” above the individual level is never an aim of natural selection, it is sometimes an accidental byproduct. The examples considered above of natural selection acting to produce negative results for the group, need, therefore, to be supplemented by other examples in which group benefits do result, but only by accident. In order for behavioral economics to fully recognize the implications of evolutionary biology for understanding behavior, it has to incorporate this type of scientific reasoning into its foundations.

Neuroeconomics

One relatively new subfield of behavioral economics is, therefore, particularly promising from an evolutionary perspective: neuroeconomics. Neuroeconomics combines analysis from neuroscience with aspects of behavioral and experimental economics and also cognitive psychology. It uses some of the methods developed by neuroscientists to study brain activity in order to investigate the relationship between economic behavior and the neural matter, the neural mechanisms, and the neural structures of the brain (Lohrenz and Montague 2008). By discovering the brain regions linked to particular thought/feeling processes, the neurological foundations of economic decision-making can potentially be better understood.

For example, in relation to neural representation of temporal discounting, or whether an individual prefers \$X today or \$X + 1 in 1 week, it has been discovered that there are two specific neural systems involved in deciding the final outcome: a more impulsive system located in the limbic system, and a more rational system located in the prefrontal cortex (McClure et al. 2004). Another study has highlighted the neurological foundations of asset investment decisions, suggesting that insula activation was linked to higher degrees of investment risk with respect to particular stock/bond choices, and that striatum activity was linked to more aggressive investment choices (Kuhnen and Knutson 2005). It has been suggested in consequence that the function of the insula is to model the hypothesized outcomes of particular risk-taking behaviors.

From the perspective of evolutionary psychology, neuroeconomics provides one potential avenue for the possibility of locating individual psychological mechanisms in specific regions of the brain, and thus the possibility of beginning to identify the concrete neurological bases of these mechanisms. Or, in other words, of creating models of the evolved computational architecture of the mind “that can be cashed out genetically” (Tooby and Cosmides 2005, 63), in order to contribute towards mapping an evolutionary psychological equivalent of *Grey’s Anatomy* (Goetz and Shakelford 2007, 15).

Conclusion

This entry, like another related entry on economists and evolutionary psychology (Barnett 2018), has attempted to present both a basic account of some of the main contributions of some well-known behavioral economists and to evaluate these contributions to some extent using concepts imported from evolutionary psychology and evolutionary biology. It has also evaluated a few basic principles of mainstream economics, like the invisible hand, in similar fashion.

From the perspective of evolutionary psychology, behavioral economics has certainly made a

sincere effort to counter some of the unrealistic assumptions and principles of neoclassical economics by presenting numerous examples of sub-optimal, irrational, biased, distorted, mistaken, and incomplete behaviors, and by providing some more realistic assumptions and principles to replace the unrealistic abstractions of much of mainstream economics. Some of these more realistic assumptions and principles overlap to a degree with those of evolutionary psychology, for example, Smith's use of the ecological rationality concept.

However, in some other areas, costly signaling theory and the handicap principle, for example, behavioral economics, has yet to fully recognize the importance of modern evolutionary concepts (Miller 2009, 91; Spence 1973), even though institutionalist economists have been analyzing conspicuous consumption since the end of the nineteenth century (Veblen (1925) [1899]). This neglect is epitomized by the work of George Akerlof and Robert Shiller, both of whom have fully acknowledged the importance of psychology for economics (Akerlof and Shiller 2009): unfortunately, this acknowledgment is only of the importance of psychology [sic], not of evolutionary psychology.

Many evolutionary psychologists would argue that what is really required in order to make behavioral economics fully realistic is for economists to embrace wholeheartedly an evolutionary approach to their subject, and place all of their theories on more solid Darwinian footings. One potentially positive breach in this regard has recently been provided by neuroeconomics. However if all of economics as a subject embraced evolutionary psychology as its underlying foundations, then it would become entirely behavioral, truly realistic, and take its rightful place as a new branch of the natural sciences (Cosmides and Tooby 2005, 585).

Synonyms

[Advantageous side effects](#)

Definition

The unintended or undesired outcomes that are beneficial.

Introduction

Side effects are often considered as undesirable. Side effects are often unintended. Side effects can be considered as by-products. When an intervention is done, it often aims at achieving a specific goal. The specific goal is often achieved through a specific mechanism at a specific site. However, the impact of an intervention may go beyond the desired or intended effect, which is often referred as side effect. In simpler terms, it can be said that the outcome of an intervention consists of desired effect and side effect (i.e., outcome = desired effect + side effect). The Merriam-Webster dictionary defines *side effect* as “a secondary and usually adverse effect (as of a drug)” and also refers to it as side

reaction (Merriam-Webster Dictionary 2006). Side effects are also commonly known as adverse effects. Side effects are often discussed in the context of different medications or interventions.

The side effect may be hazardous as well as beneficial. For example, tricyclic antidepressants like amitriptyline are often used in the treatment of depression; sedation is a common side effect of amitriptyline. Many patients report excessive sedation with amitriptyline, which is a hazardous side effect, whereas several patients with depression report insomnia too and report improvement in their sleep after treatment with amitriptyline, which can be considered as a beneficial side effect.

Beneficial Side Effects: Relevance

Understanding the biological, psychological, as well as sociocultural factors in the context of health also requires thorough understanding about beneficial side effects. An individual's basic needs (food, shelter, and sex) also have certain beneficial side effects too. Nature has designed sexual behavior in living organisms, which is meant for procreation (reproduction); some developmentally higher organisms (human) derive pleasure from sex (recreation). Here, recreation is the beneficial side effect of sex. Similarly, food and shelter are required for the survival and protection of the individual; however, pleasure is a secondary effect and biologically not intended in most of the living organisms; hence, it can be considered as beneficial side effect.

Illness (disease or disorder) causes significant impairment of functioning of the individual and compromises the productivity. However, it been seen that individuals, who are ill are often exempted from many socio-occupational roles and responsibilities. Individuals with illness also get certain disability benefits and extra care. These benefits can be considered as beneficial side effects of illness. Many patients demonstrate abnormal illness behavior or play the role of sick, being reinforced by the rewarding illness benefits (Kar and Kumar 2015).

Beneficial Side Effects: Clinical Implications

Beneficial side effects may have relevance in management of medical as well as psychiatric disorders. The effects of medications and other therapeutic interventions are judged in the patients. The effects of medications or interventions that are often acknowledged as undesired may be beneficial in certain category of clients. The beneficial side effects have been reported in various clinical research. Cleophas et al. (2002) in their study found a beneficial role of commonly used antihypertensive agents (beta blockers). They found that elderly population, who are often at risk of postural hypotension due to reduced baroreceptor sensitivity, may benefit from the use of beta blockers (Cleophas et al. 2002). Similarly, temozolomide is used as a chemotherapeutic agent for treatment of low-grade glioma; it is found to be effective in reduction of seizure frequency (Koekkoek et al. 2015). Selective serotonin reuptake inhibitors (e.g., fluoxetine) are commonly used for the treatment of depression and anxiety disorders. Fluoxetine and other selective serotonin reuptake inhibitors have the side effect of delayed ejaculation, which is found to be useful in males with premature ejaculation and erectile dysfunction (Power-Smith 1994). Hypnotic therapies are used for producing relaxation and subjective well-being. In a study on patients with chronic pain, it was found to produce certain other additional effects like decreases pain and better perceived control on pain, which are beneficial side effects of the intervention (Jensen et al. 2006). Tobacco use is one of the common substance use disorder worldwide. Nicotine is the active principle of tobacco, which is having addictive properties. Nicotine is associated with various health hazards; however, nicotine is found to be beneficial in weight regulation, ulcerative colitis, Alzheimer's disease, Tourette syndrome, as well as reducing neuroinflammation (Jarvik 1991; Noda and Kobayashi 2017). Similarly, evidences support the beneficial role of cannabidiol-enriched cannabis in the management of treatment refractory pediatric epilepsy (Dravet syndrome, Lennox-Gastaut

syndrome, idiopathic epilepsy) (Porter and Jacobson 2013).

Patients with depression, anxiety disorder, and obsessive-compulsive disorder often experience ruminations. Ruminations can be disastrous, but sometimes it becomes beneficial. Individuals, who frequently ruminate have difficulty (commit more errors) in tasks that require executive control like goal shifting. However, when they involve in tasks that do not require goal shifting and rather require goal maintenance, their performance remains better. It is a beneficial side effect of rumination (Altamirano et al. 2010). Even some evidences support that individuals who learn or listen to music show certain improvements in nonmusical domains (e.g., spatial abilities), which can be referred as a beneficial side effect of music (Schellenberg 2003).

Many a times, clinicians choose to use the side effects of a medication for a therapeutic purpose. Here, due to beneficial effect, the particular side effect becomes desirable, hence intended.

Conclusion

Beneficial role of side effect of an intervention or a pathophysiological process makes it acceptable and desirable many a times. Understanding beneficial side effects of an intervention will help the clinician in redirecting the side effects for the betterment of health.

Benefit and Cost Asymmetries

► Altruism and Costs to Altruist

Benefit Group Relative to Other Groups

Alexander Shkurko
Ulyanovsk/Nizhny Novgorod, Russia

Synonyms

Ingroup favoritism; Parochial altruism

Definition

Behavior and decisions in favor of a group with which an individual affiliates

Introduction

Living in groups implies that people develop attitudes and behaviors based on group membership. Identifying different groups is associated with asymmetrical reactions toward their members. Such asymmetries exist in various types of reactions: cognitive (biases), affective and attitudinal (prejudice), and behavioral (discrimination). Sometimes, researchers consider them as parts of the same process or use these terms as synonyms. However, most contemporary researchers agree that it is important to differentiate between prejudicial attitude and discriminatory behavior. At the behavioral level, people tend to allocate resources and make other decisions benefiting their group and prefer cooperation with the members of their group. Intergroup discrimination is thought to underlie variety of important social problems ranging from discrimination in labor or education to wars and genocide.

Ingroup Favoritism in Animals

Evolutionary origin of ingroup-benefiting behavior is supported by many facts of similar reactions in various species. Ingroup behavioral preference is common not only for primates but also for other animals such as dolphins, elephants, meerkats, lizards, birds, ants, etc., and some researchers even use similar terminology to describe behavior of microbes (Strassmann et al. 2011). In animal studies, ingroup favoritism is typically understood as a form of cooperative behavior. Typical examples of cooperation include territory defense or acquiring, joint struggle for food or mates, and communal nesting, although some researchers also include more specific forms of behavior such as grooming or interactions during water search (Masuda and Fu 2015). Importantly, animal studies show that

such cooperation is not necessarily based on kinship but can be based on more complex affiliations and social structures.

Ingroup Favoritism in Humans

Within human societies, benefiting one's own group is much more diverse and complicated, often moderated by various factors such as social status, normative beliefs, or multiple identities. One of the first experimental studies demonstrating ingroup-favoring behavior was conducted in the 1950s by a group of psychologists headed by M. Sherif. They used a field experiment in a summer camp, by arbitrary dividing boys into two groups and fostering competition between them (Sherif et al. 1961). The group membership manipulation was successful, and the members of each group easily formed both positive attitude toward ingroup and negative attitude toward outgroup, with corresponding behavioral outcomes. Later, J. Tajfel et al. (1971), using laboratory experiments, confirmed that differential reactions can be the result of absolutely arbitrary, temporary, and contextual group memberships imposed by an experimenter – what is currently known as a “minimal group.” In these experiments, participants were divided into two groups on the basis of irrelevant criteria (e.g., perceived accuracy of simple task performing or preference for Klee or Kandinsky paintings) and had to allocate resources between the members of the two groups. The study showed that participants not only tended to benefit their own group but also that they strived to maximize the *difference* in rewards between groups rather than maximizing ingroup profit. The experiments using “minimal-group paradigm” allowed to suppose that the tendency to make decisions in favor of one's own group is a direct consequence of self-categorization, i.e., identifying oneself with a particular social group or category. This means that the tendency to benefit ingroup is present even when group members don't know each other and don't interact and don't have personal benefits from the discriminating behavior.

Later, numerous psychological studies demonstrate intergroup discrimination using various methods and situations. The most common laboratory experiments use two-player games:

- Allocation matrixes: participants allocate rewards and/or penalties between ingroup and outgroup members.
- Dictator games: participants play a role of a “dictator” freely distributing rewards between him-/herself and a different player who can be ingroup or outgroup member.
- Trust games: Participants play a role of an “investor” receiving endowment which can be partially or in a whole transferred to a trustee (ingroup or outgroup), who can return any sum from the reward multiplied by an experimenter.
- Social dilemmas such as prisoner’s dilemma, when two participants simultaneously decide what share of their endowment to give to each other (Balliet et al. 2014).

In addition to laboratory experiments, psychologists conduct field studies of discriminating behavior using such methods as observation of helping behavior, hiring and housing audits, studies of policy profiling, and opinion surveys (Greenwald and Pettigrew 2014).

Most of the studies supported the view that ingroup favoritism is a common strategy underlying intergroup relation. Comparing many experimental studies using various tasks and conditions, psychologists from the Netherlands concluded that discriminating in favor of one’s group is the most frequent strategy although some studies show preference for outgroup members. Psychological studies of ingroup favoritism cover both artificial, experimentally created and natural groups based on race, ethnicity, nationality, political and organizational affiliation, support for a sport team, and others. In general, discriminatory behavior is typical for any types of group membership (Balliet et al. 2014). At the same time, other factors can affect nuances of group-based discrimination. For example, expectation of future interaction makes discriminating behavior favoring ingroup member more probable, although mere categorization is often sufficient for ingroup

favoritism. The existence of common knowledge about group membership also fosters ingroup favoritism showing that individuals care about their reputation necessary for living in a group. Social status considerations and normative beliefs can also affect the tendency to favor one’s group.

Importantly, discriminating behavior can result from two distinct types of prejudice: positive attitudes toward ingroup members and negative attitude or hostility toward outgroup members. Although they may seem to be two sides of the same process, the contemporary social psychology sees them as distinct and stresses that discrimination can result from favoring ingroup without hostility to outgroup (Greenwald and Pettigrew 2014). Moreover, identifying oneself with particular group is sufficient for discriminatory behavior and doesn’t need a clearly defined outgroup (Balliet et al. 2014).

Explanations of Ingroup Favoritism

In explaining the origins and mechanisms of ingroup favoritism, a number of theories have been proposed, mostly within social psychology and evolutionary approaches. In social psychology, ingroup favoritism is explained by social identity and self-categorization theories, balance identity theory, system justification theory, social dominance theory, uncertainty reduction theory, bounded generalized reciprocity theory, and others (Greenwald and Pettigrew 2014; Everett et al. 2015). Evolutionary approaches are generally based on mathematical models, applied to animal populations, and include direct reciprocity, indirect reciprocity, tag-based cooperation, group selection, spatial structure, and other models (Masuda and Fu 2015). Less recognized in social psychology are theories deriving discrimination from the society’s structural and normative organization (Greenwald and Pettigrew 2014).

Despite important nuances between the theories, the key discussion in contemporary psychological science is between theories deriving ingroup-favoring behavior from social identity and those focusing on actual and future interactions (Balliet et al. 2014; Everett et al. 2015). Identity-based

approaches derive ingroup favoritism from the self-categorization process and the universal motivation for positive self-esteem. If a clear distinction between ingroup and outgroup is present, whatever is the rationale for such a distinction, individuals tend to perceive themselves and others in terms of their group membership (depersonalization). When individuals perceive themselves this way, they may consider ingroup members as part of themselves, and their motivation for self-esteem or positive evaluation can project onto ingroup members. Favoring ingroup increases its power and/or superiority over outgroup, thus increasing individual's self-regard. Interaction-based approaches, on the contrary, consider ingroup favoritism as a more rational, belief-based behavior. Benefiting people having something in common with an individual can be a rational strategy when the future interactions with them are more probable than with outgroup members. Expectation of future interactions and direct or indirect reciprocity can lead to ingroup-favoring behavior.

At present, it is difficult to conclude which of the existing theories and approaches better explain complex and multifaceted discriminatory behaviors in modern societies. Most methods and studies have important limitations associated with measurement procedures, boundary conditions, representativeness of samples, lack of cross-cultural comparisons, etc. A large-scale comparison of psychological studies conducted by the Netherland psychologists led them to the conclusion that evolutionary explanations are generally more appropriate than the self-categorization theory, because they correctly predict that favoring ingroup doesn't need the clearly defined opposition between ingroup and outgroup (Balliet et al. 2014). However, such a comparison also has methodological limitations and doesn't cover studies not based on laboratory experiments.

Last decade, the development of social and cognitive neuroscience allowed a better understanding of neural mechanisms underlying ingroup favoritism. Some studies showed that even the "minimal-group" membership leads to different neural reactions to ingroup and outgroup members in a way more consistent with identity-based rather than interaction-based approaches.

For example, costly helping to ingroup members involves greater activation in anterior insula, a brain region associated with empathy (Hein et al. 2010). Another study showed that ingroup-benefiting allocation of rewards was associated with activity in the medial prefrontal cortex and anterior cingulate cortex, regions associated with self-processing and thus probably indicating that in these cases participants perceived ingroup members as part of themselves (Volz et al. 2009). However, these findings don't mean that the ingroup-favoring decisions should be necessarily determined by the only neural mechanism. Indeed, a recent study showed that reward-related neural processes can support trust and cooperation with ingroup members, whereas trust and cooperation with outgroup members involve neural systems responsible for control functions (Hughes et al. 2017).

Conclusion

Ingroup favoritism and discrimination against other group are by no means a fundamental aspect of human social behavior underlying many important social phenomena, both positive (e.g., teamwork) and negative (e.g., wars and xenophobia). The complexity of social interactions, beliefs, and identities may partially explain why so many theories of discrimination based on group membership exist and why no one of them seems to be sufficient. Studies show the diversity of human reactions toward the social groups indicating that probably the search of a single mechanism underlying them is a wrong strategy. Instead, a more integrative approaches, focusing on both identity construction and expectations of reciprocity, taking into account such factors as cultural norms or social status, is supposed to be the main direction of future research (Everett et al. 2015).

Benefit Provisioning

Christopher J. Holden
Department of Psychology, Western Carolina
University, Cullowhee, NC, USA

Synonyms

[Benefit-provisioning behaviors](#); [Benefit provisioning domain](#); [Benefit-provisioning mate retention behaviors](#)

Definition

Benefit-provisioning behaviors are mate retention behaviors that are intended to increase the incentives of staying mated to the current partner and, in turn, deter defection from the relationship. These behaviors can include things such as buying gifts for the partner, altering one's appearance, and different sexual behaviors.

Introduction

After attracting a mate, humans are faced with the adaptive problem of retaining the mate. Successful mate retention prevents other problems associated with reproduction such as cuckoldry and defection of resources (Buss 1988). Therefore, it is likely that a series of adaptations would have evolved to aide individuals in their mate retention. Indeed, an entire taxonomy of these mate retention behaviors have been identified, and these mate retention behaviors range in nature from acts that inflict costs on the partner (i.e., cost-inflicting behaviors) to behaviors that bestow benefits on the partner (i.e., benefit-provisioning behaviors; Buss 1988). Despite their difference in tactics, each of these mate retention behaviors is intended to deter the partner from defecting from the relationship.

Mate Retention Domains, Categories, and Tactics

As mentioned above, simply attracting a mate is not enough to ensure successful reproduction and the survival of offspring. Humans must also make efforts to prevent their partner from defecting from their relationship (i.e., losing a reproductive resource). It has been demonstrated that both sexes engage in extra-pair mating (Greiling and Buss 2000), as well as mate poaching behaviors (Schmitt and Buss 2001). Thus, the risk of defection is present both within and outside of the relationship. Therefore, a series of behaviors should be present to help counter these risks and should also be focused on the partner, as well as

sexual rivals. Indeed, we see that a variety of behaviors have been identified, which target the partner and/or sexual rivals.

In some of his early work, David Buss (1988) sought to develop a complete taxonomy of human mate retention behaviors. Through an act nomination procedure, 104 different acts were determined, which can be classified into two broader domains, five distinct categories, and 19 tactics of mate retention. The domains of mate retention behavior reflect whether benefits are being provided to the partner, or whether costs are being inflicted to the partner, and thus are given the names benefit-provisioning and cost-inflicting behaviors, respectively. Put another way, benefit-provisioning behaviors operate to incentivize the partner to stay in the relationship (e.g., by buying an expensive gift for the partner), whereas cost-inflicting behaviors operate to make the partner's defection from the relationship costly (e.g., by limiting their access to members of the opposite sex). Therefore, both domains operate to solve the adaptive problem of mate retention by ensuring that the partner remains invested in the current relationship while reducing the likelihood of their defection from the relationship.

Subsumed under these two domains are five distinct categories of mate retention behaviors; each of which distinguish whether these behaviors are ultimately targeted toward the partner or the rival. Under the domain of cost-inflicting behaviors are the categories of direct guarding (e.g., watching over the partner, controlling their free time), intersexual negative inducements (e.g., derogating competitors in front of the partner, manipulating the partner), and intrasexual negative inducements (e.g., derogating the partner in front of competitors, acting violent toward rivals). Under the domain of benefit-provisioning behaviors are the categories of positive inducements (e.g., buying gifts for the partner, showing love and affection for the partner) and public signals of possession (e.g., publicly commenting about the partner, using physical reminders that the partner is mated). In turn, the categories of direct guarding, intersexual negative inducements, and positive inducements can be seen as targeted toward the partner, whereas the categories of

intrasexual negative inducements and public signals of possession can be seen as targeted toward rivals. Benefit-provisioning behaviors as a whole, and the categories under benefit-provisioning behaviors, will be discussed in detail below.

Benefit-Provisioning Behaviors

Broadly speaking, benefit-provisioning behaviors involve doing things that incentivize the partner to stay in the relationship and to broadcast the nature of the relationship to rivals. Put another way, the individual is attempting to change their partner's assessment of the relationship to be more favorable and is signaling to others that their partner is taken. In turn, these actions can increase the partner's relationship satisfaction, and make defection from the relationship less likely. The various benefit-provisioning behaviors are classified into the separate categories of positive inducements and public signals of possession, as well as in the tactics that make up these categories.

Positive Inducements

The category of positive inducements includes behaviors that are intended to convey to the partner that remaining in the relationship is beneficial. For example, positive inducements include showing affection toward the partner, buying gifts, and performing different sexual behaviors for the partner. Additionally, there are a variety of positive inducement behaviors that an individual can employ to make their partner's assessment of the relationship more favorable.

Moving to the tactic level, the details of the positive inducement behaviors can fully be seen. The first tactic under positive inducements is resource display. Here, individuals are attempting to convey to their partners that they have the ability to acquire resources and provide these resources to their partner. Thus, they may do things such as buying an expensive gift for their partner or taking their partner out for a meal at an expensive restaurant. In both actions, the

individual is making an attempt to convince their partner of their ability to provide for them and any potential offspring.

The second tactic under positive inducements is love and care. Using this tactic, individuals are displaying to their partner that they are emotionally invested in the relationship. Thus, they may do things such as professing their love to their partner, acting kind or nice to their partner, or complimenting their partner on their appearance. Across these behaviors, the individual is displaying their investment in the relationship and, in turn, their willingness to invest in potential offspring.

Outside of displaying affection and resources, individuals may also make efforts to enhance their appearance. Therefore, in the third tactic of positive inducements, appearance enhancement, individuals may be doing things such as wearing fashionable clothing or using makeup or other means to make themselves more attractive. Each of these behaviors attempts to signal high mate value to the partner, which should in turn increase their commitment to their partner and decrease the appeal of attractive rivals.

Individuals may also engage in mate retention behaviors that involve particular sexual behaviors. More specifically, when employing the tactic of sexual inducements, individuals may perform sexual favors for their partner or engage in sexual activity to please their partner. Therefore, this tactic is intended to keep the partner sexually satisfied and, in turn, decrease the likelihood that they seek out mating opportunities outside of the relationship.

The final tactic under the category of positive inducements is submission and debasement. This tactic is unlike the others, as it is more of an attempt to appease the partner, as opposed to directly bestowing benefits on the partner. Using this tactic, individuals may drastically change their behavior in order to fit the desires of their partner. For example, they may be willing to forego their own desires in order to let their partner have their way. Therefore, this tactic makes the relationship more favorable by conferring the benefit of having the partner's desires met without sacrifice.

Public Signals of Possession

The second category of benefit-provisioning behaviors is public signals of possession. Here, individuals may engage in some behaviors that involve giving gifts to the partner. However, the main focus across these behaviors is to signal to others that the partner is currently taken (mated). In turn, the individual is signaling their investment to their partner. This signal of increased investment is what incentivizes the partner to remain in the relationship (i.e., this is how the benefit is being bestowed on the partner). As was the case with positive inducements, there are a series of tactics under the larger category of public signals of possession.

The first of these tactics is verbal possession signals. Here, individuals may make remarks that refer to their partner in conversation with others, particularly same-sex rivals, in an attempt to thwart any attempts to disrupt the relationship. In a similar manner, individuals may brag about their partner to same-sex rivals or describe how much they and their partner are in love to dissuade these rivals. The second tactic under public signals of possession, physical possession signals, is identical in intent. However, instead of describing the nature of the relationship to others, individuals may engage in behaviors such as kissing their partner in front of others or placing their arm around their partner as a physical sign of their commitment.

The third tactic, possessive ornamentation, takes on a slightly different approach to convey the same message to same-sex rivals. Using this tactic, individuals may engage in behaviors such as having their partner wear a ring to signify that they are taken, along with wearing other forms of jewelry and clothing to signal the status of the relationship. Therefore, this tactic involves doing things to convey to others the status of the relationship without the individual being present. In turn, although these behaviors involve giving something to the partner, their intention is focused on same-sex rivals (i.e., they are intrasexual in nature).

The tactics described above include a variety of individual acts that are included in single items of

the Mate Retention Inventory (MRI; Buss 1988; Buss and Shackelford 1997; Buss et al. 2008). Additionally, these tactics describe behaviors that a variety of individuals have reported engaging in. Therefore, it is likely that the use of mate retention behaviors varies across individuals and across different points in the relationship. Indeed, previous work has demonstrated that individual differences such as mate value, self-esteem, and personality influence the use of mate retention behaviors.

Mate Value and Benefit-Provisioning Behaviors

Broadly defined, mate value reflects the degree to which an individual possesses traits associated with reproductive success (e.g., health, youth, and beauty). That is, individuals who have a number of these traits are considered to be high in mate value. Therefore, selecting for, and retaining mates that are high in mate value would be reproductively advantageous. However, having a partner who is high in mate value may influence the degree to which individuals have to engage in mate retention behaviors. Additionally, individuals who are high in mate value may be able to engage in mate retention behaviors that their low mate value counterparts cannot.

As mentioned above, individuals mated to partners higher in mate value face the problem of retaining these partners and maintaining their access to these valuable reproductive resources. Individuals who are high in mate value are more likely to be the subject of mate poaching attempts (i.e., attempting to secure others' mates as your own) and, in turn, are more likely to defect from the relationship. Therefore, their partners should be more motivated to engage in mate retention behaviors and may be particularly motivated to engage in specific mate retention behaviors.

Indeed, it has been demonstrated that individuals mated to partners higher in mate value engage in more benefit-provisioning behaviors and less cost-inflicting behaviors (Miner et al. 2009; Starratt and Shackelford 2012). These effects

have been most extensively studied in men and suggest that men who are mated to women of higher mate value engage in more benefit-provisioning behaviors (Starratt and Shackelford 2012). Additionally women who report their partners to be high in mate value also report that their partners engage in more benefit-provisioning behaviors (Miner et al. 2009). However, one's own mate value does not appear to influence self-reported benefit-provisioning behaviors (Starratt and Shackelford 2012). That is, men who rate themselves as higher in mate value do not report engaging in more benefit-provisioning behaviors themselves. Therefore, it appears that the partner's mate value has the most direct influence on mate retention behaviors.

Self-esteem and esteem for the partner have also been used as measures of mate value (Holden et al. 2014a). More specifically, it was proposed that those high in mate value should also score higher on measures of self-esteem. Additionally, those who are high in mate value should in turn be held in a higher regard by their partner (i.e., more esteemed by their partner). Using these measures of mate value, results similar to previous studies are observed. That is, women who hold their partner in a higher regard also report that their partner engages in more benefit-provisioning behaviors and less cost-inflicting behaviors (Holden et al. 2014a). Therefore, these effects of partner's mate value on benefit-provisioning behaviors appear to be robust and stable findings.

Personality and Benefit-Provisioning Behaviors

A number of personality traits have been found to be associated with benefit-provisioning behaviors. These personality traits span multiple models of personality and include both normal and pathological forms of personality. The earliest work on personality and benefit-provisioning behaviors investigated connections between the five-factor model of personality and specific tactics of mate retention.

The five-factor model of personality (FFM; Costa and McCrae 1992) is one of the most widely

studied and influential models of personality. This model characterizes personality across the five factors of extraversion, agreeableness, conscientiousness, neuroticism, and openness. Each of these five factors has been shown to be associated with mate retention tactics under the benefit-provisioning domain. However, neuroticism, extraversion, and agreeableness all appear to be particularly associated with benefit-provisioning behaviors. More specifically, neuroticism and extraversion have both been found to be positively associated with the benefit-provisioning tactics of verbal possession, physical possession signals, and possessive ornamentation (de Miguel and Buss 2011). This suggests that those who are more sociable, but also more socially vigilant and emotionally unstable, may engage in the most of these types of benefit-provisioning behaviors. Interestingly, agreeableness was found to be negatively associated with each of these tactics that signal possession (de Miguel and Buss 2011). Therefore, it may be that individuals who score high in agreeableness refrain from using these tactics to avoid upsetting their partner. Alternatively, it may be that individuals who score high in agreeableness also see these tactics as disingenuous in nature. For the tactics of sexual inducements, appearance enhancement, and submission and debasement, an identical pattern of associations emerges. That is, neuroticism and extraversion are both positively associated with these tactics, whereas agreeableness was negatively associated with these tactics. Taken together, these findings suggest that personality influences mate retention behavior and that certain individuals may be more willing to bestow benefits on their partner.

Personality traits under the HEXACO model of personality (Lee and Ashton 2012) have also been considered in relation to benefit-provisioning behaviors. The HEXACO model of personality provides an extension of the FFM by adding a sixth factor of personality. This sixth factor of personality is referred to as honesty-humility and assesses the degree to which an individual is concerned with acting in a fair, modest, and sincere manner. Therefore, individuals who score high on honesty-humility of

personality may avoid doing things that could be considered disingenuous or false.

This aspect of personality seems to influence the mate retention behaviors that individuals use, as it has been found that honest-humility is negatively associated with the benefit-provisioning category of positive inducements (Holden et al. 2014b). This suggests that individuals who score high on this personality trait would avoid engaging in behaviors such as buying gifts for their partner, displaying their love, and enhancing their appearance to please their partner. However, it may be that these individuals avoid engaging in these behaviors in contexts where they feel as though these actions could be considered false. That is, individuals high in honesty-humility may not consider it fair or sincere to give a gift, for example, without a reason to do so. Therefore, individuals high in honesty-humility may not completely avoid these benefit-provisioning behaviors and may be concerned with how these behaviors are perceived.

An alternative explanation of this negative relationship would suggest that those who score low in honesty-humility use positive inducements as a means to manipulate or deceive their partners. Indeed, honesty-humility has been found to be negatively associated with a number of cost-inflicting behaviors, some of which involve similar forms of manipulation (Holden et al. 2014b). More importantly, low scores on honesty-humility have been found to be associated with each of the Dark Triad traits (i.e., narcissism, Machiavellianism, and psychopathy), which are characterized by having an inflated sense of self-worth, along with acting in a cold, callous, and manipulative manner (Paulhus and Williams 2002). Interestingly, the Dark Triad traits have been found to be associated with increased use of a number of cost-inflicting behaviors (Jonason et al. 2010), which would further support the idea that individuals low in honesty-humility may be using positive inducements in a manipulative manner. Furthermore, these findings suggest that various aspects of personality influence the decisions that individuals make about their mate retention behaviors and that it is worthwhile to investigate how other individual differences influence mate

retention. For example, the associations that different attachment styles have with mate retention behaviors are currently being investigated (Barbaro et al. in press).

Conclusion

Although mate retention is a universal human concern, there are a variety of behaviors that individuals may employ to retain their mates. Some of these behaviors function to increase the costs associated with defection from the relationship (i.e., cost-inflicting behaviors), whereas others function to increase the benefits associated with remaining in the relationship (i.e., benefit-provisioning behaviors). The focus of this entry has been on these benefit-provisioning behaviors, which involve doing things such as displaying love and affection for the partner, buying gifts for the partner, and engaging in various sexual inducements. Additionally, the associations between a number of individual differences and benefit-provisioning behaviors were discussed. Individuals who are higher in mate value tend to engage in more benefit-provisioning behaviors, as do individuals who are high in extraversion and neuroticism, whereas individuals who are low in honesty-humility and low in agreeableness engage in more benefit-provisioning behaviors. Therefore, despite being a universal concern, it appears as though different individuals may attempt to solve the problems surrounding mate retention in a variety of ways. However, regardless of which specific act individuals employ, all benefit-provisioning behaviors function to incentivize the partner's continued investment in the relationship.

Benefit Provisioning Domain

► Benefit Provisioning

Benefit to Another at Cost to Self

Terence Burnham
Chapman University, Orange, CA, USA

Synonyms

Benevolence; Niceness; Prosocial behavior; Selflessness

Definition

Altruism is defined as a voluntary costly act that benefits another organism, usually a conspecific (see Table 1).

Introduction

The study of altruism dates back at least to Darwin, who wrote, “Can we consider the sting of the wasp or of the bee as perfect which . . . inevitably causes the death of the insect”? (Darwin 1859) (Chapter 6). Darwin wondered how suicidal bee stings could persist – shouldn’t the stinging bees lose the evolutionary competition to other bees

Benefit to Another at Cost to Self, Table 1 Altruism in a framework of effects on self and other(s)

	Cost to another	Benefit to another
Cost to actor	Spite	Altruism
Benefit to actor	Selfishness	Mutualism

that do not commit suicide? There are currently five accepted theories that explain altruism and one open debate.

All of the accepted theories share the same underlying logic. The genes that create the apparently altruistic behavior benefit from the behavior. What appears to be altruistic is, in fact, selfish, when viewed from the perspective of the genes.

Accepted Theory #1: Kin Selection

Kin selection (Hamilton 1964) explains costly acts as benefiting genes in relatives. A bee may die when it stings an invader. This is bad for the individual bee, but good for the genes in the bee that are also likely to be shared by the other bees in the same hive. Altruistic behaviors that benefit genetic relatives help the underlying genes increase in the population.

Accepted Theory #2: Reciprocal Altruism

Reciprocal altruism (Trivers 1971) examines costly acts in the context of relationships. A person might sacrifice for a friend today and be repaid in the future. One act, examined in isolation, appears to be altruistic; when summed over the individuals’ lifetimes, however, the relationship benefits all parties.

Accepted Theory #3: Indirect Reciprocity

Indirect reciprocity (Alexander 1979; Nowak and Sigmund 1998) sees future repayment as the explanation for costly acts. Indirect reciprocity is similar to reciprocal altruism in counting costs and benefits over an organism’s lifetime. The apparent altruism is repaid in the context of

the relationship. One difference, however, is that reciprocal relationship sees the repayment coming from the individual who was helped, while indirect reciprocity allows repayment by third parties.

Accepted Theory #4: Costly Signaling

Costly signaling (Zahavi 1975) explains altruistic acts as part of a longer-term reputation management strategy. The costly act may alter the reputation of the “altruist.” The ability to help out someone in need may demonstrate, for example, health and vigor of the altruists. This perception of health and vigor might change the behavior of other organisms in a way that more than compensates for the altruist act.

Accepted Theory #5: Group Selection

Group selection (Wilson and Sober 1994) occurs when altruistic acts benefit the group in a way that also helps the genes of the altruist. If groups break up and reform with sufficient regularity, then even though the altruist does sacrifice for the benefit of the group, the genes of the altruist can increase as a percent of the overall population.

Open Debate: Strong Reciprocity

Strong reciprocity (Fehr et al. 2002) is purported as the sixth explanation for altruistic acts. For example, people in anonymous laboratory experiments in large cities will give money to strangers under some circumstances (Kahneman et al. 1986). These altruistic acts cannot be repaid through any of the five accepted theories. The participants are not kin, ruling out kin selection. The acts are anonymous so cannot be repaid through direct or indirect reciprocity. Similarly, no signals can be sent in an anonymous setting, so costly signaling is not possible. Finally, the participants are not in evolutionary relevant groups, thus ruling out group selection (Burnham and Johnson 2005). Strong reciprocity

faces continued debate about its existence and relevance.

Conclusion

The field of altruism has undergone tremendous change in the last few centuries and decades. There are five widely accepted explanations for altruistic behavior.

Benefits of Commitment and Marriage

Corry Gellatly
University of Leicester, Leicester, UK

Synonyms

Conjugality; Fidelity; Loyalty; Mating; Pair-bonding

Definition

Commitment and marriage are human behaviors that occur in the context of family formation, sexual fidelity and cohabitation.

Introduction

There are a number of benefits of pair-bonding and sexual commitment, which may have favored the evolution of monogamous and polygynous marriage systems: (1) marriage enables mate guarding, which, for men, helps to ensure paternity of the children that they commit to rearing and for women secures the resources, protection, and labor of a man; (2) pair-bonding enables reciprocal division of labor in the rearing of children, thereby optimizing the investment of parental care by each sex; (3) sexual intercourse is a powerful route for transmission of disease, which has selected against promiscuity and favored having one or a few sexual partners; (4) pair-bonding enables a reciprocal care relationship, which promotes good health and longevity.

Why Marriage?

There is much flexibility in the human mating system, with examples of monogamous, polygynous, polyandrous, heterosexual, and homosexual relationships in different cultures throughout history. However, in most cultures, we find some formal rules around the union of men and women, which we may describe as marriage. In many societies, particularly in Africa, the Middle-East, and Muslim parts of Asia, polygynous marriage is allowed, whereas in much of the rest of the world, polygyny is discouraged or illegal and marriage is a monogamous commitment. In recent years, it has been allowed for individuals of the same sex to become married in some countries, but historically, marriage has meant a commitment between a man and a woman, in which obligations of sexual, emotional, and financial loyalty are entered into.

It is often said that marriage is an institution, in reference to its central role in the structure and organization of societies. It is typical for children to be raised in a household which is headed by a married couple and often for those children to leave the household when they themselves enter into a marriage. It is also seen that factors linked to social status, such as wealth and employment, affect the desirability of individuals in the marriage market (Goldman 1993; South 1991). However, biological factors, such as health, age, and height, may be much more important to the choice of a marriage partner (Kiernan 1988; Lipowicz 2014). It is likely that much of the decision-making about a potential marriage partner occurs at a subconscious level, for example, individuals may evaluate the level of genetic similarity or dissimilarity in a potential partner through their body odor (Kromer et al. 2016; Roberts et al. 2008).

Taking an evolutionary perspective, we may assume that the organizational structure of society is to a large extent evolved, which is not to say that the institution of marriage has been hard coded into our genetic makeup via natural selection. It is to say that the social structures that currently exist have succeeded through the trials of many generations, with cultural institutions contributing to that evolution, but not necessarily dictating it. The evolutionary hypotheses that have been put forward in relation to marriage are here dealt with in turn:

Marriage Is a Form of Mate Guarding

In polygynous and monogamous marriage, other males are excluded from sexual encounters with the wife, thereby ensuring the paternity of the children that the husband commits to rearing. It is possible to view marriage as an institutionalized form of mate guarding, which has evolved because the most dominant males are the most successful when it comes to getting married, and it is in their interests to defend in law what might be viewed as the ultimate form of paternalism. But while there is evidence that healthier and more successful males are more likely to marry (e.g., Lipowicz 2014; Goldman 1993), it may be too simplistic to argue that males are the only ones

who are mate guarding within marriages. It has also been argued that women practice mate guarding to secure the resources of their husband, as these are often vital for the rearing of children (Buss 2002).

In comparative studies, we find that monogamous species consistently show less dimorphism than polygynous ones, including in primates (e.g., Clutton-Brock 1985), most likely because males are not engaged in violent combat for access to mates in monogamously pairing species, as compared to polygynous ones. It has been argued, based on the fossil record, that sexual dimorphism declined over the course of human evolution, suggesting that a transition from polygyny to monogamy may have begun prior to the evolution of *Homo sapiens* (Lovejoy 1981). A difficulty with this argument is that polygyny does occur in many human societies, although it may not necessarily be the dominant form of marriage, with many monogamous marriages also occurring within such societies (White et al. 1988).

An issue to consider with mate guarding is that it can imply that one partner is exerting control over the behavior of the other to enforce their loyalty. In these circumstances, it may be in the interests of the guarded partner to circumvent the enforcement and seek extramarital partners. The question of how human behavior is evolved to deal with these issues is an active area of research in evolutionary psychology (e.g., Buss and Shackelford 1997; Shackelford et al. 2006).

Marriage Facilitates Reciprocal Division of Labor in the Raising of Children

The raising of children requires investment of time, energy, and resources – the same time, energy, and resources that are required for one's own survival and well-being. In economic theory, it has been argued that there is a quality-quantity trade-off in the raising of children, whereby parents face a choice of having more children or investing more in fewer children (Becker 1960; Becker and Lewis 1973). The principle that humans must raise socially competitive offspring means that parents must balance family size against offspring success (Lawson and Mace 2011). If we also take into account sexual

selection – whereby individuals of the highest perceived quality are those who gain the greatest reproductive success – we see the importance of investing in the development of children. For parents, the question is how to provision children with an optimal level of investment while still producing enough children that the risks of not leaving any genetic heirs are too high.

It has been argued that humans would never have evolved without the combined effort of males and females to raise children, given the very long phase of infancy and the demand that this places on parents (Hrdy 2011). This is also the argument put forward by Fortunato and Archetti (2010) based on inclusive fitness theory—that monogamous marriage is an evolutionarily stable strategy for the allocation of resources to the next generation, promoting the survival of offspring by not fragmenting inherited resources. The importance of female choice and faithfulness in the development of monogamous pair-bonding systems (as compared to promiscuous mating systems) is emphasized by Gavrilets (2012), because providing for a female and her offspring becomes a viable strategy for low-ranked males to increase their reproductive success.

Marriage Reduces Transmission of Diseases Through Sexual Intercourse

The close proximity and exchange of bodily fluids involved in sexual intercourse is a powerful means by which human diseases are transmitted. There are numerous examples of bacterial (e.g., gonorrhea and syphilis) and viral sexually transmitted diseases (STDs) (e.g., genital herpes, hepatitis, and HIV). The impact of STDs ranges from irritation to premature death, with many causing chronic debilitation, infertility, and even damage to unborn children. It is for this reason that natural selection may favor monogamous over promiscuous behavior, simply because those with a tendency for promiscuity suffer higher mortality and morbidity through disease (Bauch and McElreath 2016).

In smaller groups, with a small degree of mixing with other groups, disease transmission would have been less of a problem, as may promiscuity, but as the human ancestor transitioned to

a bipedal ape, able to cover long distances and make contact with far flung groups, the potential for the transmission of disease would have increased, and we can hypothesize that less promiscuous behavior would have been favored by selection. In the modern world, STDs are abundant, and there is little doubt that promiscuity, including unprotected extramarital sex, increases the human disease burden (e.g., Reniers and Watkins 2010).

Marriage Is a Reciprocal Care Relationship

A number of studies have identified that married persons tend to live longer than singles (e.g., Hu and Goldman 1990; Lillard and Waite 1995), though the exact reasons for this are not clear. There are broadly two theories to explain the phenomenon. The first is that marriage itself has a protective effect on survival, through the support network and socioeconomic advantages that it brings. The second theory is that there is selection into marriage of individuals who are likely, even prior to marriage, to live longer, because of a high-quality genetic or physical profile, which also makes them attractive to the opposite sex.

It has proved very difficult to disentangle the protective effect of marriage from selection into marriage, because individuals move in and out of the married category, while the impact of becoming widowed or divorced may be more harmful to health and longevity than remaining as a lifetime single (Ben-Shlomo et al. 1993; Tucker et al. 1996). It appears, however, that marriage is more beneficial for men, in terms of its effect on longevity, particularly when men are married to younger women (Drefahl 2010; Foster et al. 1984; Gellatly and Störmer 2017).

Indications are that women exhibit a stronger preference for an older man in their first marriage than men do for a younger woman (Bozon 1991), which possibly relates to the desire for a “provider.” However, it may be the case that women are choosing men who, having lived longer, have demonstrated their survival and their ability to acquire skills or wealth. It might similarly be in men’s interest to select among older women, who have had longer to demonstrate their survival abilities, except that there is a shorter reproductive

window for women, which causes men to select more heavily on traits associated with fertility.

Conclusion

The importance of family formation and raising of children is no doubt fundamental to the existence of marriage, but we must also consider that reduction of disease transmission, mate guarding, and reciprocal care are important contributory factors to the existence and benefit of marriage.

Benefits of Profound Kinship Connectedness (and Problems from a Lack Thereof) Through an Evolutionary Mismatch Lens

Jiaqing O.
Department of Psychology, Aberystwyth
University, Aberystwyth, Ceredigion, UK

[Advantages of having close blood and affinal relationships](#); [Disparity between the prehistoric environment and the current one](#); [Issues associated with not having intimate bonds with one's relatives](#)

Definition

Being physically and emotionally close to one's kin was instrumental for ensuring well-being and

survival in the brutal ancestral context. Although the contemporary world is generally a much more secure and socially progressive place to live in, the lack of adequate support from one's kin (which are relatively more evident in the present day as people become more independent from their kin due to greater perceived safety and opportunities) might nonetheless still lead to adverse consequences for the affected individual (as relatives are still principally more likely to aid him/her across a variety of life domains than non-kin).

Introduction

Throughout the course of evolutionary history, *Homo sapiens* have generally lived in small closely knitted groups comprising predominantly of biological and affinal relatives (Hill et al. 2011). Within these groups, both biological and affinal relatives have a vested interest evolutionarily in the survival and reproductive success of the individual (the latter category of relatives being indirectly concerned as a result of a shared interest in the well-being of one's descendant/s with whom they are genetically affiliated) (Hughes 1988). Maintaining a strong emotional connection with these kin and living one's life in close proximity to them were predictably helpful in reducing the risk of injuries/death and in enhancing the chances that one would subsist long enough to propagate his/her genes into the future generations in the typically harsh, unpredictable prehistoric world (where food was infrequently available and threats from predators/rival tribes were prevalent); vice versa.

However, due to the tremendous transformations in terms of the physical and societal conditions in the recent era (e.g., the virtual elimination of all natural predators in numerous parts of the world and the perceived availability of a massive array of attainable resources in the globalized information age), many humans are now venturing away and residing independently from their kin (while not always maintaining a close connection to them) (e.g., Hank 2007). Such a relative lack of physical and emotional

bonds with one's kin are expected to result in a range of negative repercussions primarily because *Homo sapiens* are not yet evolutionarily prepared (in terms of cognitive and social capacities which will require countless generations to evolve) to function just as competently in a context that is largely devoid of kin (O 2018a).

Effects of (a Lack of) Close Connections with Kin in the Modern Environment

Despite massive changes in the social and physical spheres of the world since prehistory, humans in the present context are still believed to be more likely to help and support their kin across a vast range of life domains than non-kin as the welfare of the former is pivotal in the direct/indirect dissemination of one's genes into succeeding progenies (Hughes 1988). Indeed, a variety of studies conducted on modern-day humans has corroborated such a premise. For instance, kin were reported to be more inclined to provide an individual with considerable amount of useful resources (e.g., lending him/her a massive sum of money) in times of need as compared to non-kin (including friends) in contemporary societies (e.g., Fitzgerald and Colarelli 2009). In addition, modern-day humans have revealed that they were generally more prepared to assist relatives, rather than those who were not related to them, in their search for a stable partner (Jonason et al. 2007); and research work has appeared to suggest that they were also more committed and nurturing when looking after their kin's offspring as compared to those from non-kin (e.g., Sallnäs et al. 2004). Likewise, contemporary humans have also indicated a greater desire to save their kin (instead of non-kin) from a serious life-threatening situation (e.g., saving him/her from a building that was on fire) (Burnstein et al. 1994).

In light of such a diverse array of highly-valuable assistance that could potentially be rendered by one's kin, it is imaginable that the absence of intimate physical and emotional

bonds with them in the present day would lead to a host of negative outcomes for the individual. Because many individuals presently have kin who are located relatively far away, and that many may also not have a strong emotional connection to their relatives due to a lack of regular interactions over the years (e.g., Hank 2007) – which was a factor that has been empirically shown to be positively related to one's propensity to help (Rachlin and Jones 2008), these individuals are expected to be more at risk of experiencing unresolved issues regarding insufficient resources (e.g., they might have encountered some forms of financial difficulties and are struggling to raise enough money to clear their large debts within a strict time frame) than their counterparts who are residing near to (and have maintained close links with) their kin. Analogously, these individuals are believed to be more likely to struggle to find a suitable long-term partner (and could hence remain single and childless as a result) or could conceivably find it harder to cope with balancing work and parenting duties if they have children, in the absence of the valuable assistance from their kin. Furthermore, these individuals are likewise postulated to be more likely to die without their kin around them if they are unfortunate enough to be involved in a life-threatening situation (e.g., being trapped in rising waters after a flood). In fact, it was predicted that these individuals are also more susceptible to be successful suiciders (if they are actually contemplating to kill themselves as a result of some severe emotional distress) due to their faraway kin not being nearby to intervene adequately in a swift manner (O 2018b).

Conclusion

On the grounds that kin were generally more inclined to be concerned about one's welfare (as compared to non-kin) across human prehistory (even in the modern day), the evolutionarily novel relative absence of close physical and emotional contact with these individuals are believed to significantly affect one's functioning (and

possibly survival) and reproductive success in the current context.

Definition

Direct and indirect benefits of engaging in short-term mating relationships.

Introduction

According to sexual strategies theory (SST), men and women evolved to adopt mating strategies that were aimed to solve recurring adaptive problems faced ancestrally (Buss and Schmitt 1993). Since men and women differ in their reproductive biology, sex differences are a fundamental component of SST, and therefore, the biological differences between the sexes influences the temporal dimension of mating strategies. For women, the heavy investment of pregnancy and child rearing means that reproduction is a costly process, whereas men only invest in sperm production, and paternal investment is not always certain. These sex differences in reproduction factor into the mating strategy utilized by men and women, as maximizing reproductive success may be favored by the least investing sex and maximizing parental investment may be favored by the more investing sex. Although humans engage in both short-term (i.e., casual sex, extra-pair infidelities) and long-term (i.e., pair bonding, long-term commitment) mating strategies, what benefits can be obtained from utilizing a short-term mating strategy in both sexes? What

characteristics in a potential mate do individuals rely on when assessing short-term mating relationships? And lastly, what evidence exists on utilizing a short-term mating strategy in both sexes?

Men's Short-Term Mating Benefits

Biologically, men are the least investing sex, which according to parental investment theory should influence their differential reproductive success in being less discriminate in mate choice (Trivers 1972). Being less discriminative in mate choice does present challenges. One adaptive problem men have faced in mating has been in identifying which women were fertile, considering the role of cryptic or concealed ovulation. Women do not display overt cues indicating fertility as other nonhuman primates do, therefore recognizing cues that indicate fertility would have been an advantage for men's reproductive success. Additionally, being able to identify which women are accessible while decreasing commitment and risks associated with mating have been key restraints. Given these key restraints, mating strategies should be influential in maximizing reproductive success, such as pursuing a short-term mating strategy that aims to pursue quick sexual encounters with minimal commitment. For instance, men's mating psychology that express desire for an increased number of partners, interest in sex after a short period of time of knowing women, and relaxing their mate preferences for short-term mating have been supported by research using sexual strategies theory (Buss and Schmitt 2019).

What are some of the benefits associated with pursuing a short-term mating strategy in men? For men, maximizing differential reproductive success through indirect benefits (i.e., genetics) is an advantage in short-term mating. Men can increase their reproductive success by 50% if involved in a short-term mateship, which is of course dependent upon the survival of the child from conception considering the rough environmental conditions that would have been present during ancestral times (Buss and Schmitt 1993). Nevertheless, an

immense amount of research, both descriptive and experiential, have found strong support for men's desire to engage in short-term mating and to allocate importance to characteristics associated with genetic benefits (e.g., physical attractiveness). This suggests that the heritability of physical characteristics is an important consideration for men when pursuing short-term mating strategies. Physical characteristics, such as full lips, clear skin, symmetry, and low waist-to-hip ratios, are informative traits men rely on to solve the adaptive problem of concealed ovulation, and they are often the standards of attractiveness that are placed on women (Buss and Schmitt 1993).

Empirical evidence has shown men's prioritization of physical characteristics for short-term mating. Sexual dimorphic features in women, such as feminine facial characteristics, are often preferred over masculine facial features during a short-term mating context (Grammer and Thornhill 1994; Little et al. 2011). Feminine facial features advertise reproductive cues, and therefore, preferences to these features would directly be associated with men's reliance on physical traits in short-term mating for maximizing reproductive fitness. However, there are differences in the importance of physical characteristics when asked to prioritize facial features in comparison to bodily features. Although feminine facial features are often preferred, given the role of estrogens in facial femininity, they may convey reproductive value, as opposed to current reproductive fertility. Experimental studies have shown that men prioritize bodily over facial cues when asked to consider a potential mate for a short-term over a long-term mating context (Confer et al. 2010; Jonason et al. 2012; Perilloux and Cloud 2019). Studies incorporating behavioral ratings, such as eye tracking procedures, have also shown men's interest to specific features associated with fertility where visual attention is centered on ideal waist-to-hip ratios (Dixson et al. 2011). Research using fMRI has highlighted important areas of the brains associated with reward processing, most notably the nucleus accumbens, when viewing women who advertise physical features associated with fertility (Platek and Singh 2010).

Although certain physical features may connote fertility in women, men's preferences for these features is influenced by life history factors, such as ecological conditions. The ecology of one's environment provides cues of the availability of resources, and individuals may trade-off choosing a partner with good genes over one who is willing to invest. Under a harsh ecological condition, choosing a partner who is willing to invest may be a better strategy, since sharing resource pools may provide offspring with better survival, whereas in a safe ecological condition, conditions are conducive to better survival and choosing a partner with good genes may be a better mating strategy (Geary et al. 2004), favoring short-term mating. In contrast, in harsh ecological conditions, short-term mating may be an optimal strategy, as the risk of mortality is high and cues in the ecology may prompt individuals to adopt a strategy favoring early reproduction (Belsky et al. 1991). For short-term mating, men have shown a preference to feminine women during harsh ecological conditions, suggesting that ecological cues prompt a faster reproductive strategy in difficult environments. Safer environments prompt men to choose women who display masculine facial characteristics, where men choose low-quality but high-investing mates (Little et al. 2007).

For men, pursuing a short-term mating strategy increases the likelihood of reproductive success because multiple matings are more likely to lead to more offspring as opposed to a long-term investment with one partner (Trivers 1972). Although men have an evolved preference for short-term mating given the different adaptive problems faced between the sexes, mating behaviors reflect these preferences. For instance, men are more willing to agree to a sexual proposition when asked by women; however, when women are given the same proposition by men, the response is not mutual (Clark and Hatfield 1989). Men are more likely than women to seek out prostitution services, and their preferences for physical characteristics in prostitutes are reflected in short-term mating research. For instance, prostitutes that display ideal physical features, such as low BMI, medium breast size, and youthfulness

are more valued, as indicated by the prices of services (Prokop et al. 2018; Sohn 2016). Altogether, men's prioritization on physical characteristics indicate that benefits associated with short-term mating are geared to maximize reproductive success as evidenced by preferences to features associated with fertility and reported behaviors for casual sex.

Women's Short-Term Mating Benefits

Since women are the most investing sex biologically, they gain more from being discriminatory in choosing the best fit mate. By being choosy in mate choice, they can choose a partner that displays high quality or a partner that displays parental investment. When pursuing a short-term mating strategy, women have faced mate selection problems, such as finding a mate who can provide immediate resources, good genetics, and mates who may serve as backups from current relationships (Buss and Schmitt 1993). According to strategic pluralism theory, short-term mating carries the trade-off of choosing a mate who displays good genetics over parental investment. Since women's reproductive success is dependent on ovulatory status, mating strategies may be calibrated to maximize reproduction during peak fertility. Several studies have shown that women's mating strategies influences their preferences for types of men that display features of good genetics and men who are can provide immediate resource acquisition, and short-term mating strategies may be preferred when fertility is optimal.

What are some of the benefits associated with pursuing a short-term mating strategy in women? One benefit of short-term mating is the heritability of good genetics from choosing a mate who displays high quality features. Good genes, such as masculinity, muscularity, and symmetry, are features women find ideal when pursuing a short-term mating strategy, known as the good genes hypothesis (Buss and Schmitt 2019). Sexual dimorphic features, such as pronounced brow ridges and jaw line, are phenotypic markers of increased testosterone, and given testosterone's immunosuppressant effects, women use these

cues in men as honest signals of immunocompetence (Folstad and Karter 1992). That is, men who display these masculine features can afford the immunosuppressant effects of testosterone. Preferences to these physical characteristics have been largely supported by research, both descriptive and experimental. When asked to choose between men who display masculine versus feminine facial features, women choose masculine facial features when pursuing short-term mating (Jones et al. 2018). Other features associated with good genes, like physical attractiveness, has also been preferred by women when considering men for a one-night stand compared to a long-term relationship (Kenrick et al. 1993). Since short-term mating is likely to lead to immediate sexual access, women's mate choice has shown to maximize physical characteristics that signal genetic heritability if reproduction were to occur.

However, preferences for masculinity in men may reflect women's short-term mating strategy in solving the adaptive problem of immediate resource acquisition. Men who display formidable features such as muscularity are considered stronger, and strength is an important contributor in resource acquisition (Puts 2010) and men's attractiveness (Sell et al. 2017). Men with muscular (i.e., mesomorphic) body types are preferred and are rated as more attractive by women with short-term mating strategies (Provost et al. 2006, 2008). Women's preferences to muscularity have also been reflected in their viewing behavior when assessing men as potential mates. Using eye tracking to assess attentional biases to men's physical characteristics, women focus most of their viewing time to the chest region of men's bodies, a region associated with formidability (Durkee et al. 2017; Pazhoohi et al. 2019). Additionally, women who pursue short-term mating strategies have shown to attend to the chest region longer (Garza and Byrd-Craven 2019), suggesting that short-term mating strategies not only influences mating preferences but actual behavior.

Short-term mating preferences in women have been shown to be affected by the reproductive cycle. In humans, reproduction can only occur when fertility is high, and mating effort has been shown to shift during times of peak

fertility, known as the ovulatory shift hypothesis (Thornhill and Gangestad 1999). This hypothesis suggests that during peak fertility, women should prefer men with characteristics associated with good genetics, such as physical attractiveness and muscularity (Gangestad et al. 2007). Research has shown that women assess men with ideal physical characteristics as more attractive for short-term mates near ovulation (Gangestad et al. 2007). A large-scale meta-analysis study has also supported fertility shifts in short-term mating to high-quality men. When assessing a partner as a short-term mate, preferences for physical characteristics indicative of genetic quality were strongest during peak fertility, more specifically for body masculinity and men who display social dominance (Gildersleeve et al. 2014).

Other research has pointed to the role of life-history strategies and women's calibration of mating strategies for men with ideal physical traits. For instance, when considering ecological conditions, it may be beneficial to pursue a short-term mating strategy when there are limited resources. Experimental research has demonstrated that women prefer masculine facial features for short-term relationships in safe compared to harsh ecological contexts (Little et al. 2007; Marcinkowska et al. 2018), suggesting that safer environments provide women with increased offspring survival, therefore channeling their investments to high-quality men. This trade-off for good genes over parental investment suggests that women do not have more to gain from an investing partner if resources are readily available. This finding has also been found in cross-population research when considering measures of safe environments, such as high health and economic indices. Women in more favorable environments prefer men with more masculine facial features (Marcinkowska et al. 2018), and dispositional short-term mating seems to influence these preferences. Since favorable environments are associated with greater sexual openness, women with short-term mating motivations are more likely to express preferences for more masculine partners (Marcinkowska et al. 2018). In contrast, women from harsh ecological conditions have shown to prefer short-term mating when closer to ovulation (Kim et al. 2018), in

line with the perspective that harsher environments decrease offspring survival and pursuing a mate who can invest may not be the most optimal strategy over maximizing reproduction (Belsky et al. 1991). In harsh environments, mortality risk is high, and therefore, choosing a partner who displays good genetics may increase the viability of offspring survival in a difficult environment (Belsky et al. 1991). Furthermore, preferences for masculine men for short-term mating may be a product of securing direct benefits (i.e., resource acquisition, protection) from a partner in a difficult environment.

A function and benefit of short-term mating in women is the possibility of mate switching. The mate switching hypothesis proposes that women engage in short-term mating when currently involved in a relationship to secure a backup mate in case a relationship ends, make it easier to leave the current relationship, trading up in mate value, or to assess one's own mate value in the current mating market (Buss 2016; Buss and Schmitt 2019). There are many reasons as to why women would engage in mate switching behaviors, but one key predictor is relationship satisfaction. Relationship satisfaction predicts women's infidelity and desire for other men regardless of fertility status (Gangestad et al. 2005), suggesting that switching mates for good genes may not explain short-term mating behaviors in women currently in relationships. Other research has shown that interest in other men when currently in a relationship is influenced by sex with current partners, as lack of sex with current partner increases desire for other men (Pillsworth et al. 2004). Moreover, women who reported their partners low in sexual attractiveness were more likely to report extra-pair desires; however, this was not likely to occur if they reported their partners to be high on investment attractiveness (Pillsworth and Haselton 2006). Women involved in mate switching may be interested in characteristics associated with long-term investment that are not currently provided by their current partner. Being involved with a partner who is not economically successful and meeting a potential mate who is more successful than their current partner are all inclinations associated

with infidelity (Greiling and Buss 2000). Women have also reported their ideal traits in an affair partner, and they include characteristics indicative of investment, such as being honest, stable, and dependable (Greiling and Buss 2000; Kenrick et al. 1990).

Conclusion

Short-term mating strategies provide different benefits to each sex. For men, maximizing reproductive success is a benefit, as shown by their preferences to key physical features that indicate fertility and their willingness to maximize mating opportunities. For women, acquiring indirect (i.e., good genes) and direct (i.e., resource acquisition, protection) benefits seem to be influential reasons to engage in short-term mating. However, human mating is incredibly nuanced, as contexts, culture, and individual differences drive preferences for engaging in short-term mating strategies. Nonetheless, sexual strategies theory (SST) provides a framework for why humans engage in different mating strategies, as well as identifying the benefits obtained from choosing one strategy over another.

demonstrates how traits that harm individual organisms can be maintained by natural selection; thus, an organism can, therefore, increase genetic representation in future generations even if that organism fails to reproduce (Liddle et al. 2011). There is evidence to suggest that suicide terrorism can function to benefit the fitness close kin.

Benefits to Kin

Definition

One evolutionary theory of suicide terrorism proposes that the act is committed in order to benefit the close kin of the attacker.

Introduction

Suicide terrorism is a politically motivated aggressive act wherein the perpetrator willingly sacrifices his or her life with the goal of inflicting harm on typically civilian casualties. One evolutionary theory of suicide terrorism proposes that terrorist organizations manipulate followers into embarking on suicide missions in order to benefit genetic kin. This theory of suicide terrorism is rooted in kin selection (Smith 1964), a form of altruism based on Hamilton's rule ($rb > c$) where r is the degree of genetic relatedness, b is the reproductive benefits to related kin, and c is the cost to the agent (Hamilton 1963). According to this theory, an organism should act altruistically when the reproductive benefits to its kin are greater than the costs of the act to the organism. Kin selection

Theoretical Overview: Suicide and Benefits to Kin

Though there is scant data on suicide in non-human animals, self-sacrifice through death is evidenced in a variety of species such as sterile castes of the order Hymenoptera for the purpose of colony defense (Preti 2007). Likewise, in *E. coli* self-sacrifice might function to limit the transmission of a bacteriophage to related organisms (Refardt et al. 2013).

In regards to humans, psychologist Denys deCatanzaro proposed that one with low reproductive potential who is imposing net fitness costs on biological kin would improve his or her inclusive fitness by committing suicide (de Catanzaro 1981; 1984; 1991). Though theorists have not directly applied deCatanzaro's inclusive fitness model to suicide terrorism, aspects of the model are relevant. Moreover, the end goals are identical: to increase fitness by increasing the reproductive success of close genetic kin at a cost to the self. A suicide terrorist should have relatively low reproductive potential (e.g., poor prospects for mating opportunities) such that the reproductive benefits to kin should outweigh the costs to the suicide attacker. There are two means through which attackers might benefit their kin that when combined are unique to the context of suicide terrorism: monetary compensation and heightened familial reputation.

Terror organizations such as Hamas and Hezbollah promise to provide financial compensation to the families of prospective suicide attackers. As of 2002, Hamas, for instance, paid the families of suicide attackers between \$10,000 and \$25,000 and often in addition offered medical services. In cultures such as those in the Middle East, this money can contribute to bride's wealth

wherein the groom provides payment to the bride's family in the form of money, goods, or other services. Thus, financial gains to one's siblings can promote their reproductive success, which might factor into the decision of one to opt into suicide terrorism or for a parent to encourage offspring to execute such missions. Blackwell (2006) modeled the inclusive fitness benefits of suicide terrorism, finding that theoretically suicide terrorism can incur inclusive fitness benefits, particularly in large, middle class families with many males. In fact, suicide attackers and their families tend to be wealthier on average than their social counterparts (Krueger and Malečková 2003).

Heightened social reputation is another asset that is bestowed upon the families of suicide attackers that might benefit their fitness. Motivations such as these could be fostered through cultural values such as collectivism and honor-based codes of conduct, which are endemic to regions where suicide terrorism is found. In fact, honor cultures strongly encourage retaliation against external threats and aggressors for the sake of both the individual and their social group, and evidence suggests that such strategies could be evolutionarily stable in certain contexts (Nowak et al. 2016). Suicide terrorism is a form of political retaliation typically employed to combat more powerful opponents (Pape 2005; Hafez 2006). In these communities, members celebrate suicide attackers as religious "martyrs" and heroes of their homeland, and they might devote shrines and websites to honor their sacrifice (Hafez 2006). The reputational benefits often extend to the kin of the suicide attackers, which could confer reproductive benefits such as additional income and access to mates. At present, however, data is lacking to sufficiently demonstrate that the reputational benefits of suicide attack translate into inclusive fitness benefits.

Conclusion

Empirical evidence indicates that suicide terrorists might be motivated to benefit their kin through the attack, thus increasing their inclusive fitness. However, more research is necessary to confirm these models.

Physical signals of attractiveness in humans

Introduction

The work of Bernhard Fink and his collaborators has a clear focus on the sexual signals that are revealed via our physical bodies. Based on the assumption that what is deemed physically attractive is by and large universal, Fink's research attempts to uncover what adaptive information these attractive physical traits are signaling to potential mates.

Facial Attractiveness, and 2D:4D Ratio

One such physical trait is our faces, and what they may signal in mate choice. In a review,

Fink and Penton-Voak (2002) examined previous research in an attempt to identify what features of faces make them attractive. They conclude that the key features include symmetry, indicators of hormone levels (such as testosterone), and "averageness". Evolutionary psychology suggests that such features act as reliable cues of an individual's health, an important trait in mate choice, thus making them attractive (Fink and Penton-Voak 2002).

Drawing on one of the above facial features, symmetry, Fink et al. (2004) examined what this may signal about an individual's developmental stability, which could account for its role in mate choice. Using 2D:4D ratio as a proxy indicator of fetal hormonal environments, they found that this was significantly related to facial asymmetry, but in opposite directions for men and women. Fink et al. (2005) further investigated how 2D:4D ratio interacts with facial features differently between men and women. By comparing key facial characteristics with 2D:4D ratio in a sample of men and women, Fink et al. (2005) found that prenatal hormone levels affect men and women's faces differently. Also, although 2D:4D ratio affected men and women's face shapes in a similar manner, this effect was three times stronger for men. From these findings, it can be concluded that facial (a)symmetry and shape acts as an important and honest signal of quality due to its links to the early developmental environment of individuals (in terms of fetal testosterone/estrogen levels), thus accounting for their importance in attractiveness judgments.

Furthermore, Fink et al. (2001) examined if skin texture of faces affects their perceived attractiveness. It was found that men's judgments of the attractiveness of women's faces varied in response to differing skin texture, which, Fink et al. (2001) conclude, shows that skin texture acts as an honest cue of good health and fertility. Likewise, Fink et al. (2006a, b) showed that facial skin coloration also influenced attractiveness ratings. They found that skin color distribution influenced perceptions of women's age (thus acting as a signal of youth) and also judgments of their attractiveness and health.

Body Morphology and Movement

However, what do facial features related to attractiveness reveal about the rest of the body, and how may the rest of the body influence physical attractiveness? To answer the former question, Fink et al. (2006b) sought to find out how facial indicators of psychological traits of attractiveness, masculinity, and dominance may relate to the actual physical trait of strength. They found that men's hand-grip strength did indeed positively relate to women's ratings of their perceived levels of all three psychological traits. Therefore it seems that there exists clear links between signals from faces and from bodies that can play a key role in mate choice. This is further supported by Fink et al. (2010) who found that ratings of attractiveness, masculinity, and dominance in men's faces were positively correlated with the same ratings in the bodies. Therefore Fink et al. (2010) conclude from this that it is the same mechanisms that cause the development of such cues in both men's faces and bodies, thus contributing to them both being important sources of sexual signals of attractiveness in mate choice.

In terms of how the body may physically signal attractive traits for mate choice, Fink et al. (2014) found a positive relationship between men's body symmetry and their physical hand-grip strength. As physical strength will be a desirable trait in sexual selection (for both inter- and intrasexual selection) and be an honest indicator of quality, it will develop together with other indicators (such as body symmetry) to play a role in attractiveness in men. More recently, Fink has explored how perceptions of physical signals of quality in bodies are influenced by the signaler's body movements. In an early investigation, Fink et al. (2012) took measurements of men's personality traits and also recorded them dancing to a simple rhythm. After anonymizing the recordings, these were then shown to a sample of women to rate for the quality of the dancing. Fink et al. (2012) found that women's assessments of the quality of dancing correlated with a number of these traits, suggesting that such body movements may be able to act as an honest signal of other underlying

characteristics. Subsequent research shows that dance quality can also signal traits that positively relate to men's attractiveness, such as physical strength (Weege et al. 2015). This suggests that future research into sexual signaling of physical traits in men should incorporate moving as well as static cues, as humans of course do in the real world.

Conclusion

The work of Bernhard Fink and various colleagues have been pivotal in making the connections between physical signals in our bodies, what these signals relate to, and how and when these are viewed as attractive in mate choice. This is central to the view of evolutionary psychology that what is attractive is universal and has an adaptive value in sexual selection. Furthermore, recent investigation into movement via dancing quality offers a novel approach to research into attraction, and through utilizing modern technological advances, Fink and colleagues offer a clear sense of how humans realistically view potential partners in mate choice.

Better Never to Have Been

Simon Reeve
Oakland University, Rochester, MI, USA

Synonyms

[Antinatalism key text](#); [Antinatalist philosophy of David Benatar](#)

Definition

A book by the philosopher David Benatar, published in 2006, advocating the antinatalist claim.

Introduction

According to David Benatar, it is “better never to have been” and it would be morally better if the human race was extinct. That is, coming into existence always causes serious harm to the individual, and therefore, procreating is always morally wrong (the antinatalist claim). In this way, it would be best if the human race became extinct as then there would be no one to suffer this harm. This is not to say that the antinatalist claim is one that promotes human death (mass suicide, genocide or speciocide, devastating natural disasters, etc.). In some cases, the antinatalist would support the death of an individual but typically only when the individual is experiencing immense suffering and would prefer to die sooner rather than later. This is not a particularly radical view and many, if not most, people would concur in at least some possible cases. Instead, the antinatalist is against the creation of new lives and not (necessarily) the premature end to existing lives. The word “premature” is particularly significant as, again, it is important to keep in mind that every single person that is born will die at some point. Therefore, if the antinatalist ideal was realized, this would actually reduce death as there would be no more people to die. In this way, the view that death is typically a bad thing is proposed to be supportive of the antinatalist claim as procreators effectively create a death every time they create a life: As anyone who is born will eventually die, extinction would technically minimize death overall as once extinction is achieved, there will be no more death.

Antinatalism

Although death is – more often than not – an extremely unpleasant and painful experience, it is not the only suffering an individual will

experience by coming into existence, and it is suffering that is particularly central to the antinatalist claim. If you consider an existing person first, when they experience pain, it is clearly bad and when they experience pleasure, it is good. Likewise, when they are deprived of experiencing pleasure, it is bad and when they are “deprived” of experiencing pain, it is good. These axiological values could theoretically be weighed and summed to produce an overall axiological value of a particular life relative to an alternate life. That is, it is easy to evaluate a person’s life as better if they experience more pleasure and/or less pain than an alternative life. However, this logic relies on comparing one possible life to another possible life and has the underlying assumption that there *has* to be some sort of life: It is this aspect that the antinatalist claim refutes. Instead, the antinatalist claim considers the axiological value (the abstract value and “goodness” of all varieties) of *any* possible life to *no* life at all. When there is no person, there is nobody who can be directly benefitted or harmed. Therefore, the point of reference for a comparison is drawn solely from the scenario when a person would have existed. Essentially the claim is comparing two possible worlds rather than two possibilities within one world: one world in which a person exists and one in which that same person does not exist. We then evaluate which world is better with reference to the interests of this individual (Benatar 2013, p. 125). As the individual only exists in one of these two possible worlds, that world is our point of reference for comparison.

As it is possible to assign an axiological value to one possible life compared to another possible life, the antinatalist reasoning can be illustrated by comparing two such cases and then comparing these to a world where the individual did not come into existence at all. Firstly, when a world where the individual experiences a great deal of pain (a lot of bad) and experiences very little pleasure (very little good) to a world where they never came into existence at all, it is reasonable to conclude that the latter is better. More so, the lack of the pain that *could* have been in this world (had the individual been born) is argued to be a good thing, even though there is

nobody who directly benefits from not experiencing this pain. That is, the absence of pain is considered a good thing even if there is nobody to experience the pain.

Second, when a world where the individual experiences a little bit of pain (a little bit of bad) and experiences a great deal of pleasure (a lot of good) is compared to a world in which this person never came into existence, it may, at first glance, seem reasonable to conclude that the former is better. However, according to the antinatalist claim, this logic does not follow: Benatar asserts that for this world to be better, we would be stating that the *lack of the pleasure* that could have been in this world is clearly a bad thing, even though there is nobody who is deprived of experiencing this pleasure. However, if there is nobody who is deprived of experiencing this pleasure, then the lack of pleasure in the later world is not, according to the antinatalist claim, axiologically bad. Conversely, it is proposed that the lack of the small amount of pain that the individual would have experienced is still a good thing even though there is nobody who is benefitted by not experiencing this pain (as with the first world considered but to a smaller scale). Therefore, even in this case where there would only be a little pain, it is still proposed by the antinatalist that it is actually also better if this person had never existed: That is, it is not bad that they do not experience the pleasure they would have if they had existed (no matter how much pleasure there would have been), but it is still good that they avoid the pain they would have experienced if they had existed (no matter how small the amount of pain would have been). Although it is clearly not *as much of a good thing* that this person did not exist in the second world than it is that they did not exist in the first world, in both cases not existing, it is still deemed better than existing. Essentially, this logic forms the basic asymmetry in axiological value between possible worlds that justifies the antinatalist claim: Coming into existence always causes harm to the individual because the absence of pleasure is only bad when there is someone who is being deprived of that pleasure, but the absence of pain is good even if there is

Scenario A (X exists)		Scenario B (X never exists)
(5) Absence of Pain (Good)	(1) Presence of Pain (Bad)	(3) Absence of Pain (Good)
(6) Absence of Pleasure (Bad)	(2) Presence of Pleasure (Good)	(4) Absence of Pleasure (Not bad)

Better Never to Have Been, Fig. 1 Replication of “The basic asymmetry amplified” (Benatar 2013; pg. 136)

nobody around to benefit from its absence, so it is not possible for the axiological value of existing to outweigh not existing (see Fig. 1; the asymmetry manifests between cell #4 and cell #3 and #6). Benatar’s antinatalist claim has been challenged by other philosophers. For example, Bradley (2010) points out that when considering “betterness,” the laws of logic (citing the Albert Brogan and G. H. von Wright view) dictate that the presence of pleasure in existing people is *better* than the absence of pleasure in nonexistent people, even if the absence of pleasure in non-existing people is considered neutral (see also Harman 2009).

Conclusion

“Better Never to Have Been” is a book by the philosopher David Benatar advocating the anti-natalist claim that it would be better for the human race to stop reproducing and become extinct. The argument is based on a logical asymmetry when comparing two theoretical worlds: one where a person exists and the other where they do not exist. Although the presence of pleasure in the first world is a good thing and the absence of pain is a good thing in both worlds, the absence of pleasure is only a bad thing (as deprivation) in the world where the person exists and the absence of pain is greater (i.e., no pain at all) in the world where they do not exist. The text is highly controversial and its logic challenged.

Biases

Dallas Novakowski¹ and Sandeep Mishra²

¹Department of Psychology, University of Regina, Regina, SK, Canada

²Faculty of Business Administration, University of Regina, Regina, SK, Canada

A cognitive bias refers to any systematic deviation from accuracy or “rationality” in judgment and decision-making. Some commonly examined biases include the following: *confirmation bias* (the tendency to interpret new evidence as confirming one’s existing beliefs); *hindsight bias* (the tendency to overestimate one’s ability to have forecasted known outcomes); *base rate neglect* (the tendency to ignore general frequency information and instead focus on specific information); and *sexual over-perception* – the tendency for men to over-perceive sexual interest in others.

Simon (1955) first proposed that people use simple mental shortcuts (*heuristics*) for judgment and decision-making, leading to what appears to be biased decision-making. The “heuristics-and-biases program” achieved greater prominence as a result of the publication of Tversky and Kahneman’s (1974) seminal *Science* paper. Tversky and Kahneman’s work has largely focused on understanding heuristics and biases as *errors* in judgment and decision-making. That is, heuristics and biases were seen as violations of the standard utility-maximizing “rational” economic model of decision-making. However, this approach of understanding heuristics and biases as “errors” rather than products of adaptive decision-making processes has been widely criticized, especially by evolution-minded researchers.

A more contemporary, evolution-informed understanding suggests that cognitive biases may arise for three possible reasons. First, the use of mental shortcuts (*heuristics*, which reflect bounded rationality) may have systematic breakdowns, which lead to errors. Second, some errors in decision-making may have had (historical) asymmetries in their fitness cost, with the consequence that organisms evolved to favor errors that had the lowest net cost (manifesting in *error management biases*). Third, people may appear to make systematic errors because the laboratory tasks or evaluation standards used to measure such “errors” were unnatural and incompatible with the design of the human mind (manifesting in *artifacts*; reviewed in Haselton et al. 2009). In the following, we review each source of cognitive bias briefly.

Biases as a Product of Bounded Rationality

Traditional economic utility-maximizing models of decision-making assume that actors have accurate and complete information, enough time to assess all decision alternatives, and enough cognitive capacity to go through a complete deductive process. The *bounded rationality* approach suggests that most decisions are products of simple

heuristics that are cognitively efficient and robust to diverse environments (Gigerenzer and Selten 2002). Moreover, research has demonstrated that heuristics often have high ecological validity. Some evidence suggests that heuristics operating on limited information are superior to decisions made with complete information (e.g., Gigerenzer and Goldstein 1996; reviewed in Todd and Gigerenzer 2007). However, while effective in a wide variety of circumstances, heuristics are prone to breakdown in systematic ways, leading to biases in judgments and decision-making (Tversky and Kahneman 1974).

The hindsight bias, for example, has been demonstrated to be at least partly a product of bounded rationality. This bias has been hypothesized to be a product of a memory-updating heuristic when decision-makers do not have access to memory cues. Supporting this hypothesis, the hindsight bias is reduced when participants are given relevant memory cues (reviewed in Blank and Nestler 2007). Some theorists argue that biases resulting from heuristics are due to the methodological neglect of decision environments. They argue that cognitive abilities were designed for specific environments and problems, and that these abilities cannot be properly understood or assessed when studied out of context (e.g., Gigerenzer et al. 1999). Expanding on the importance of ecological rationality, evolutionary theorists posit that ancestral environments should also be considered when investigating biases.

Error Management Biases

Error management theory (Haselton and Nettle 2006) suggests that some biases reflect adapted preferences for errors with lower fitness costs. When inferring the presence or absence of a target in a stimulus, judgments can be falsely positive or falsely negative. However, false positives and false negatives cannot be simultaneously eliminated. Traditional signal detection theory (Tanner and Swets 1954) posits that instruments should instead be biased toward the least costly error. Error management theory thus integrates evolutionary logic and signal detection theory.

Error management theory posits that biases are shaped by historical fitness costs. For example, the sexual over-perception bias can be explained by the potential costs of searching for a receptive mating partner (Haselton and Buss 2000). Falsely perceiving sexual interest (false positive) costs an individual courtship effort, whereas failing to perceive sexual interest (false negative) costs a reproductive opportunity. Since men do not have to make the metabolic investment in gestation and lactation, a missed reproductive opportunity carries a far larger cost than a wasted courtship attempt (Haselton and Buss 2000). Error management theory posits that certain biases exist because of environments and challenges that are proxies of fitness. However, biases can also arise when humans reason in environments that are unfamiliar to the evolved mind.

Biases as Artifacts

Some evolutionary theorists argue that many documented instances of biases are actually artifacts of unnatural research designs. These theorists argue that humans are functionally rational when reasoning about evolutionarily relevant information (e.g., Cosmides and Tooby 1996). However, biases can occur when either the problem format or the problem content is incompatible with a mind shaped by natural selection.

Human bias is often inferred from inaccuracy when estimating probabilities or likelihoods (Tversky and Kahneman 1974, 1983). Biases stemming from innumeracy, for example, might only occur because humans are not suited to reasoning with percentages and probabilities. Humans should be more proficient at estimating likelihoods when they are framed as discrete, naturally occurring events (Gigerenzer 1997; Cosmides and Tooby 1996). For instance, organisms must understand their probability of success when deciding whether to hunt a specific animal. However, organisms did not experience rates of success as percentage values or odds ratios. Instead, successes and failures were likely historically recalled as individual events. For example, consider someone projecting the success of a

hunting attempt. It is likely that inference of the probability of success should be a product of the frequency of recent attempts (e.g., three of the last ten hunting attempts were successful), rather than a product of a percentage probability (e.g., 30% of hunting trips end in success). Consistent with this hypothesis, people are more accurate at making predictions when questions are framed as natural frequencies, rather than probabilities (reviewed in Gigerenzer and Hoffrage 2007). The extant research suggests that many instances of bias might not necessarily be errors. Rather, such biases may be better understood as the consequence of the incompatibility between stimuli and mind.

The heuristics and biases program has demonstrated that human reasoning often deviates from utility-maximization and norms of rationality. Biases can impact outcomes in judicial, economic, and medical settings (e.g., Harley 2007). It is thus important to understand the functional, evolutionary reasons for bias in order to develop effective interventions. Theories that only assume that biases are the result of flaws in the human mind are limited in their explanatory power. By contrast, ecological and evolutionary theories have produced many testable (and empirically supported) predictions about the nature of bias. In particular, cognitive mechanisms that manifest in biases reflect the importance of the historical (and contemporary) structure of decision environments, as well as the importance of problem formats and contents.

Definition

“Big Man” is used to signify both an important individual as well as one large in size.

Introduction

The phrase “Big Man” is used to signify both an important individual as well as one large in size, both historically and cross-culturally (Ellis 1992; Murray and Schmitz 2011; Sahllins 1963). Contemporary English language is also riddled with phrases that highlight an association between size and status (or the lack of it) – “a man of stature,” “standing tall,” “he was belittled” – and the phrase “high status” itself incorporates a vertical dimension. This conflation of size and status across many different language groups and cultures has a rather straightforward explanation: On average, those in position of power or high in status tend to be taller and bigger than those who are not. Positive associations between size and status have been observed in all kinds of cultural groupings, from hunter-gatherer groups to agricultural populations to industrialized societies (Ellis 1992; Murray and Schmitz 2011; Sahllins 1963; Stulp and Barrett 2016).

Why Are “Big Men” Big Men?

There are several reasons why bigger or taller individuals tend to reach higher status than those who are smaller and shorter (see discussions in Stulp and Barrett 2016; Stulp et al. 2012, 2015). First, bigger individuals may have some physical superiority over others, allowing them greater access to resources (which typically is taken to signify some form of “status”). This is often corroborated with cross-species evidence: In many species, larger males may display a substantial advantage in fights with other males over access to resources and females (Ellis 1994). A second reason is that size, or at least height, is positively associated with health (Stulp and Barrett 2016). Such an association can arise when favorable childhood growth conditions (plenty of nutritional resources during development) lead to a both a healthier and larger physique. Good childhood conditions may also favor the development of better cognitive skills, leading to a positive association between height and measures of intelligence, thus offering a third reason why taller men may occupy positions of higher status (Silventoinen et al. 2006). In societies with heritable material wealth (e.g., land, money), the association between size and status can also arise because of a fourth process, whereby an individual inherits both favorable growth conditions and social status. All of these reasons, either alone or in combination, may account for positive cross-cultural patterns between size and status, and why individuals of high status are often described as “big men.”

In contemporary industrialized populations, where physical force is prohibited by law, physical superiority is likely to play a marginal role in achieving higher status (Stulp et al. 2015). Nevertheless, consistent positive associations are observed between male and female height and various proxies of social status. An additional factor that might contribute to these positive associations is biased perceptions relating to height and overall body size: Taller individuals, particularly men, are perceived to be more attractive, intelligent, competent, dominant, and better leaders (Blaker and Van Vugt 2014). The increased social status accorded to taller individuals (on average) may thus arise due to

preferential treatment in response to such perceptions. Indeed, studies suggest that tall individuals experience positive discrimination in the labor force and also that people seem to favor tall (er) individuals as their political leader (Stulp et al. 2013; Murray and Schmitz 2011). Thus, the positive association between height and status in contemporary populations may be at least partly due to perceptions and biases that do not necessarily correspond to an individual's ability. Indeed, although consistent positive associations are observed between height and several measures of social status (most readily explained by favorable childhood circumstances), the strength of these associations is typically very low in magnitude. The perceptual links between size and status may therefore be somewhat out of proportion to the actual link between the two. Ironically then, the use of phrases like “Big Man” and “belittled” may actually contribute to the persistence of an association between size and status, because such phrases undoubtedly feed into perceptions associated with size.

Conclusion

“Big Man” clearly is not a gender-neutral term, which reflects the fact that men historically have been more likely to hold political power and leadership positions, not least because men are physically much stronger than women (on average), which seems to be one of the requirements for leadership in earlier times. The times, though, are changing: Women in industrialized populations often achieve high status and positions of leadership, and on some measures of status (such as education) women outrank men in several populations. Moreover, in more equal societies, the gap in height between those of low and high status is closing. If this trend continues, phrases like “Big Man,” “a man of stature,” and “standing tall” will continue to be less relevant.

Multilingualism

Definition

Speaking two language, with varying degrees of proficiency.

Introduction

Language is the means by which a message is communicated. Language can be spoken, heard, written, and/or read. Language consists of phonology (rules governing how sounds are formed in words), morphology (units of meaning), semantics (vocabulary and rules governing word combinations), syntax (formation of sentences), and pragmatics (how language is used in interaction and the intent or meaning of messages). This entry will address issues of monolingualism and bilingualism with regard to the evolution of language. The foremost difference is that a monolingual has fluency in one language, while bilinguals speak two languages, with varying degrees of proficiency, i.e., perfect ability is not required. Bilinguals speak their languages at the levels that are needed, not always with proficiency.

According to Chomsky (1965), most individuals are born with the capacity for learning and speaking their “native” language, or the predominant language used within their community. The nativist perspective stated that the ability to learn grammar and language is “hardwired” into everyone’s brain. Language develops without being formally taught; all human beings share a common set of cognitive abilities such that cultural

variabilities are negligible. Pinker and Bloom (1990) suggest that language is attributable to human biology, rather than culture: “like echolocation in bats or stereopsis in monkeys, not like writing or the wheel.” However, individuals who are raised in feral conditions or severe neglect with little to no exposure to language early in life demonstrate very limited language acquisition (Fromkin et al. 1974); therefore, it seems that language is a combination of nativist and exposure factors.

Darwin’s theory of natural selection explains how an organism’s possession of heritable traits allows them the ability to adapt, more readily survive, and reproduce. Language is adaptive because it allows for communication among the group, cooperation, and social currency (Hagen 2008). However, Whorf (1956) believed that differences in language, grammars, and how the languages are used in different cultures affect the manner and way in which the speaker perceives the world and their environment. The products of the mind are a function of the social communities where individuals interact with each other. Thus, it is important to consider sociocultural influences on how the brain functions.

This entry will identify (a) historical influences on the acquisition of language, such as evolution of physiological improvements that promoted language, (b) cultural pressures that promote monolingualism and bilingualism among different social groups, and (c) the adaptive function of bilingualism while promoting the view that speaking more than one language produces differences in how the brain is functionally organized.

Physiological Adaptations Promoting the Evolution of Language

Numerous hominid fossils allow us to draw inferences as to how speech and language originated. The examination of prehistoric fossils demonstrates that the human species has undergone extreme and detailed physical mutations in the brain, cranium, pharynx, laryngeal, and supralaryngeal vocal tract physiology (SVT; Hagen 2008). The discovery of findings such as the

bipedal female adult hominid from 3.2 million BCE, *Australopithecus afarensis*, and even older (4.0–4.2 million BCE) hominid species, *Australopithecus anamensis* and *A. ramidus* (4.4 billion BCE), has allowed researchers to examine vocal change physiology across time. Hagen (2008) found that *A. ramidus* displayed a mixture of hominid and ape features, and, even though australopithecines walked upright like humans, they had chimp-like skull shapes and characteristics, which would suggest that they may have not been any more cognitive and linguistically developed than other nonhuman primates. For instance, the chimpanzee (our closest genetic relative) is not capable of speech and vocal capabilities as humans are. They are physically unable to form vowels or consonants due to variances in their vocal tracts (Hagen 2008). If ancient hominid ancestors were nonlinguistic, yet biologically similar to modern humans, what happened between the hominid species and current *Homo sapiens* that allowed the genetic makeup to foster speech and language? As cited in Hagen (2008), Lieberman (2006) posits that this transition seems to be related to cranial capacity. There was a hefty increase in size of the cranium for early australopithecines, from 400 cc (3 million BCE) to 800 cc (2 million BCE) for *Homo habilis* and 1000 cc for *Homo erectus* (1.5 million BCE) and then finally 1400 cc for modern *Homo sapiens* (as cited by Hagen 2008). Another physiological change noted would be the development in the flexion (bending) of the base of the skull. This is thought to not only permit a longer pharynx (i.e., the throat) but also constitutes a lower positioning of the larynx (below the epiglottis, responsible for phonation, articulation, and speech) in the throat (Hagen 2008). Skull fossils including the larynx from those of the *Homo ergaster* (1.8 million BCE; same species as *Homo erectus*) were found to have limited elastic capacity compared to more recent species such as found by Tattersall (1995) *Homo heidelbergensis* (1 million BCE; as cited by Hagen (2008). The resulting lower position of the larynx assisted in the production and evolution of speech and, consequently, spoken language; however, this adaptation also came

with difficulties. Lieberman (1998) pointed out this lower location of our larynx makes it much more likely that humans will choke on food; humans are the only mammals that cannot breathe and swallow at the same time (as cited by Hagen 2008). Dean et al. (2001) found this alteration in turn led the human supralaryngeal vocal tract to require a smaller jaw, lowering our potential for nutrient processing and resulting in less efficient mastication as our nonlinguistic predecessors, who used their jaws primarily for food crushing (as cited by Hagen 2008). However, the evolutionary adoption of one trait for a purpose other than what natural selection had intended results in transforming our vocal tract from one of an eating to a resonating and sound-producing chamber capable of speech. It is still unknown whether prehistoric hominid beings possessed language capabilities. Bickerton (1990) suggested that the *Homo erectus* was in fact capable of a simpler form of language: deemed protolanguage or essentially language without syntax. The *Homo habilis* skull suggests hemispheric specializations, suggesting some language abilities were present in the *Homo erectus* (as cited by Hagen 2008). In the following section, we will consider how some communities developed predominantly monolingual or bilingual language usage.

Geographical Pressures Leading to Either Monolingualism or Bilingualism

Homo sapiens began migrating to Eurasia from Africa around 120,000 BCE and most likely possessed full linguistic capabilities. The population of humans at this time was much fewer in number, estimated at no more than one tenth of one percent of our current population (Gamble 1993). However, when these social groups started increasing in number, maintaining administrative infrastructure became problematic, and consequently the groups began to splinter and disperse. This likely led to geographical separation among the groups, ultimately resulting in loss of contact. Their languages drifted, and groups formed their

own dialects and eventually their own languages. The social structure of nomadic hunter-gatherers would have facilitated an engagement with other groups, and mastering languages from other groups is a critical evolutionary adaptation. This multiple language adaptability would have promoted the maintenance of social bonds among various cultures and prevention of conflicts. As Hagen (2008) specified, the primary language is used to resolve intra-cultural conflicts (or conflicts within the same social community), and second languages are utilized to resolve intercultural conflicts (or conflicts across social communities). The diversity of languages that emerged was in an effort to found and preserve cultural differences that would provide an improvement of survival. Not only would the acquisition of another language demonstrate a magnitude of social respect, but it would also help maintain intercultural affairs (such as bonds, trade, etc.) as well as a way to avoid hostility (Hagen 2008).

From a historical perspective, bilingualism has gone through many recurrent trends and extinction. A potential reason for early ancestors not learning more than one language might have resulted from population “bottlenecks” that the world was experiencing. For example, the massive eruption of a volcano in Sumatra around 75,000 BCE (Lake Toba eruption) resulted in a population drop so detrimental that only a few thousand humans were spared. Having such a small population, and paired with a nomadic lifestyle, more than one language would not have been a necessary skill to acquire (Hagen 2008).

The standard for most children to become fully fluent in a language usually requires about 2–3 years of exposure and use for conversation. Since these nomadic individuals could not contribute to this type of (linguistic and geographic) consistency, the need to learn multiple languages did not seem to be of benefit. The ebb and flow of monolingualism and bilingualism over time may have resulted from dispersion of hunter-gatherers (i.e., promoting monolingualism) and consequently at later times the forming of communities and cities (promoting bilingualism).

Sociocultural Pressures Leading to Either Monolingualism or Bilingualism

The cooperative disposition of the egalitarian communities would facilitate the need for communication. As Jacques-Rousseau alluded to in *The Social Contract*, the egalitarian sense of equal freedom is something we are born with, and people only deviate from this for the sake of utility (Rousseau and Gourevitch 1997). Learning another language would promote mutual respect in addition to fostering fellowship, trade, and resolution of intergroup conflicts (Hagen 2008). Contrary to this idea of cooperation, the English philosopher, Hobbes, believed that individuals are inherently violent, and morality does not exist. In Shermer’s (2004) book *The Science of Good and Evil*, he touched on Jane Goodall’s evidence of this primitive and aggressive behavior when observing our distant ancestors, the *Pan troglodytes* (chimpanzee), in Tanzania (as cited by Hagen 2008). Even though both Rousseau and Hobbes describe common behavior in response to varying predicaments, survival of the species favors the Rousseau dynamic. The species is much more likely to survive and flourish when there is cooperation and concern for others present.

Alternatively, bilingualism has been extinguished through cultural perceptions not tied to geographical limitations. Foreign languages have never been extinguished in any other country as quickly as in the United States. The concept of speaking one language is much more prevalent in the West, whereas most of the world’s population is bilingual. From the colonial days to the mid-twentieth century, the essence of “one nation, one language” was the thought process, even suggesting that this mentality would facilitate a sort of linguistic perfection. Americans during this time believed that immigrants coming to the United States should speak only English; the dedication to monolingualism was seen to be representative of faithfulness, harmony, and democracy among the country. Nebraska, for example, has had laws (from 1919) banning teaching of any foreign languages below ninth

grade. The state of Nebraska organized a campaign in its honor known as “Good English” and even had students quote language loyalty oaths. Some individuals posit that the mentality behind this type of action was related to the common misconception that bilingualism created mental confusion and damaged immigrant children’s ability to adapt to their new surroundings.

This perspective continued on as recently as the early twentieth century. The prevalent belief was that bilingualism does not benefit individuals, but instead hinders cognitive abilities of dual-language persons, especially in children. A common misconception is that genetic differences between races prohibited immigrants to learn English, which in turn was perceived as a lower intelligence level. The other explanation was that since the child spoke in their foreign language at home, and English at school, perhaps the dual vocabulary and lexicon impeded each other. Peal and Lambert (1962) shed light on this issue and found that, when controlling for social class, bilingualism actually produced higher results on a number of intelligence tests. They not only found that two vocabularies actually improved comprehension for bilingual individuals but also enhanced multiple higher cognitive abilities including concept formation (Liedtke and Nelson 1968), metalinguistic awareness (Cummins 1978), and code-switching, which demonstrates intellectual advantages (Hughes et al. 2006). The next section explores neuroanatomical differences and cognitive benefits of bilingualism as a positive adaptation and a mechanism to improve brain function and plasticity.

Hemispheric Lateralization and Specialization in Language Processing

The first identification of the brain being acknowledged as the center of language was indicated in the *Edwin Smith papyrus*, in approximately 3500 BC (Ahlsén 2006). The specific neuroanatomical location was later discovered by Broca upon autopsy of two of his patients; both had suffered severe language-speaking deficits, yet

retained relatively good comprehension abilities with impaired speaking abilities. Both had injuries to the inferolateral frontal cortex (Broca 1861). He surmised that linguistic symptoms were caused by these left hemisphere lesions, and therefore language was located, and lateralized, in the left hemisphere. Later, Carl Wernicke (1874) identified the temporal-parietal regions as the processing center of language comprehension, an area separate from spoken language. He also proposed the idea of language functions localized in the gyri (brain convolutions). Other evidence has supported this belief of language-related initiation, specifically in areas such as the gyri (lingual and fusiform), middle prefrontal areas (such as the dorsolateral prefrontal cortex), the insula, and even middle and inferior temporal gyri and temporal pole (Obler and Gjerlow 1999). Processing language, as well as the language acquisition center, is predominantly associated with the language centers located in the left hemisphere of the primary and secondary auditory cortices, more specifically the perisylvian region of the left hemisphere (Hagen 2008). The right hemisphere has been labeled the nondominant hemisphere as noted by studies indicating that significant speech, language, and reading disabilities occur when lesions are located in the left hemisphere (Ardila and Ostrosky-Solis 1984). Abutalebi et al. (2001) suggested that activation of the right hemisphere occurs in mirror regions during language tasks. Although evidence for right hemisphere function of certain linguistic abilities has been found, 97% of nondisabled right-handed people and 70% of nondisabled left-handed people have left hemisphere lateralization (Obler and Gjerlow 1999). This presumption of left hemisphere lateralization was identified in Lenneberg’s 1964 study of language loss in young children with left hemisphere brain injuries. Lenneberg et al. (1967) later proposed evidence to support a critical period hypothesis (CPH), a theory in which language acquisition and linguistic ability are tied to biological age, cutoffs, and language fossilization (i.e., language growth stopping at a certain age). This hypothesis is explored in the context of early versus late second language acquisition. Lenneberg

et al. (1967) postulated the critical period consisted of 2 years to about 14 years of age. Patkowski (1980) examined the concept of a sensitive period, which references a preferred age for second language acquisition and windows of opportunity for best acquiring language. He investigated the idea of native-like acquisition of syntax in a nonnative language and hypothesized that it would be more difficult to achieve native-like fluency unless the individual began to acquire the second language before the age of 15. He surmised that this native proficiency is not necessarily dependent on the age of puberty, but rather the utilization of sociolinguistic conditions prior to puberty, such as exposure, practice time, etc. Consequently, it is possible to acquire a second language after this "critical period"; however, it is somewhat harder to reach native-like fluency in the second acquired language after the sensitive period (Patkowski 1980).

Neural plasticity may be an underlying mechanism promoting greater fluency with earlier second language (L2) acquisition. Plasticity also mediates recovery of language functioning such that when second language acquisition occurs before 7 years of age, language is more resilient to disease and injury compared to those who learn after this sensitive period (Fabbro 2001). Hagen (2008) states that almost all childhood aphasia studies have shown 75–100% recovery rates. In addition, Paradis (1977) found that after a stroke there were different degrees of rehabilitation in each language for bilinguals. Hernandez et al. (2000) stated that there have been no clear rules in relation to recovery patterns; however, they found that factors such as first language learned, language use before aphasia, and language dominance all played into varying degrees of language recovery. While these studies demonstrate the influence of age of acquisition and plasticity on first language (L1), and L2, language localization is also an important element to consider.

Brain organization and language localization for monolingual and bilingual individuals is not a straightforward proposition. The left hemisphere has been known for most expressive and receptive language functions. However, brain

localization for bilingual individuals may differ for their L1 and L2. For example, Gomez-Tortosa et al. (1996) presented a case study of a bilingual patient with selective impairment in L1 (but not L2) after surgery to remove a lesion in her left perisylvian area of the brain. Alternatively, L2 could be localized in the right hemisphere. Dehaene et al. (1997) identified, using fMRI, that although L1 seems to be mediated by a similar brain network in individuals they assessed, the L2 produced activation in left and right temporal and frontal areas, occasionally restricted only to the right hemisphere (namely, the right superior temporal gyrus and superior temporal sulcus). Perani et al. (1996) used positron emission tomography (PET scans) and revealed that when late second language learners listened to L1 (i.e., their native languages), it activated brain areas that are not apparent in L2 (i.e., the second language) for late second language acquisition learners. These brain areas included both left and right temporal lobes, left inferior parietal lobe, and left inferior frontal gyrus. These findings demonstrate variation in patterns of localization and lateralization of function. A meta-analysis of 66 studies suggests that age of acquisition was a strong predictor of lateralization (Hull and Vaid 2007). When L2 learning occurred before the age of 6, bilateral organization was common, whereas after the age of 6, both languages were predominantly left lateralized. Hull and Vaid (2007) suggest that when infants are learning two languages simultaneously, pragmatic cues are needed to differentiate between the two languages, which underlies the right hemisphere involvement. Alternatively, they suggest that the extensive requirement for learning two languages promoted involvement of both hemispheres and produced automaticity in these areas. The age of 6 is a specific time in brain development during which neural wiring and pruning take place (Huttenlocher and Dabholkar 1997, as cited by Hull and Vaid 2007). Right hemisphere involvement in language acquisition after this point may be less efficient and involves less automaticity than left hemisphere involvement. For example, recent research utilizing a timed picture-naming

task provided evidence that early second language learners exhibited faster response times and speed accuracy compared to those who learned their second language later (Kohnert et al. 1998).

Conclusion

Both physiological adaptations and sociocultural processes favor and promote bilingual speaking in communities. Evolutionary forces across time have warranted the opportunity for our brains to evolve and be ready for the learning of language such that our vocal tracts are not only necessary for eating but evolved for speech. Although the downsides include not being able to breathe and swallow at the same time, increased likelihood of choking on food, and decreased nutrient processing (Hagen 2008), the benefit of developing such complex vocalizations as symbolic language far outweighs these costs. Brown et al. (1985) postulated that the use of symbolic language allowed for complex thought and heightened the cognitive capacity of the human brain as evidenced in the increasing size of the cranium (as cited by Hagen 2008) and volume of prefrontal brain matter (Schoenemann et al. 2005). With these physiological adaptations in place, humans were poised to begin a new phase of adaptation involving complex oral linguistic communication within and across social communities. As humans began migrating to other areas and splintering due to instabilities in large community sizes, languages diverged and evolved as well. However, some communities had the opportunity to utilize second language acquisition through sociocultural interaction, whereas others were constrained by geographical isolation or cultural mores to speak only one language. For those who had geographical access to communities speaking another language, learning a second language was adaptive because it promoted development of intercultural bonds and access to resources.

Not only would speaking two languages be adaptive socioculturally but also cognitively and physiologically. A pattern emerges in the research on the areas of the brain associated with speech

and language. The left hemisphere is specialized for language processing, but bilingual brain organization is dependent on factors such as age of acquisition, exposure, and practice; consequently, learning a second language is recommended before the age of six (Hull and Vaid 2007) or before one reaches puberty (Patkowski 1980) due to greater brain plasticity. Indeed, the acquisition of a second language has profound effects on the brain, leading to improvements in executive function (Bialystok 2015), task switching (Prior and MacWhinney 2010), conflict resolution (Bialystok et al. 2012), and metalinguistic awareness (Galambos and Hakuta 1988), as well as and serving as a protective factor against age-related dementia and Alzheimer's disease (Bialystok et al. 2012). The neurological benefits of bilingualism have been found to increase gray matter volume in bilinguals, compared to monolinguals (Olulade et al. 2016).

In a world that is becoming more globalized, the benefits of bilingualism cannot be ignored. While geographic limitations may inhibit direct communication with others, communities can be easily accessed through the Internet. Exposing children to other languages early in life and fostering communication digitally as well as in person could lead to lasting positive changes in the brain and cognition, as well as promote cultural competence. Bilingualism can be adaptive since it allows individuals to have exposure to other cultures through different languages, in addition to establishing a sense of interconnectedness.

Definition

Binocular disparity is a binocular depth cue produced by a difference in retinal projection of the

same object onto left eye and right eye retinas as a result of a horizontal separation of the eyes.

Introduction

Stereopsis, or the perception of the “true” location of the objects in depth obtained on the basis of binocular information, requires the two eyes to be located at different lateral positions so that they receive slightly different projections onto their retinas when focused on the same point in space (Fig. 1). In addition, stereopsis requires coordinated eye movements; disorders that interfere with this coordination such as amblyopia and strabismus lead patients to report perceiving two images of a single object (diplopia or double vision; Otero-Millan et al. 2014). Although the importance of binocular disparity in achieving depth perception in primate vision is well established, its role in vision of other animals is less clear, particularly for animals with laterally located eyes.

Binocular Disparity, Fig. 1 Geometry of binocular disparity and stereopsis. As both eyes simultaneously fixate on a point *F*, it falls on their foveae. The point *A* lies closer to the observer (i.e., before the point of fixation) than the point *B*; therefore, the projections of these points fall on different locations in the *left* and the *right* eyes. Consequently, the distance from the fixation to the projection of each point (denoted as *a-f* or *b-f*) will be different for the *left* and the *right* eyes; this difference is termed binocular disparity and can be used for recovering depth information

Use of Binocular Disparity for Depth Perception in Humans and Nonhuman Animals

When a person looks at a certain point, their eyes fixate on that point, and its projection falls directly onto a fovea of each eye (Fig. 1). Because of the lateral separation of the eyes, the objects in front of the fixation point and behind it will project to a slightly different points on the retina; for example, the retinal distance between points A and F in Fig. 1 is smaller for the left eye than for the right eye (Ponce and Born 2008). This binocular disparity serves as a basis for stereopsis.

Although binocular disparity has been most actively studied in context of depth perception, it also has other benefits. For example, stereoscopic use of binocular disparity improves detection of camouflaged animals against a background that is similar in color and in texture (Wardle et al. 2010). Binocular comparisons also aid in recognition of occluded objects by assisting in discriminating true object borders from the borders created by occlusion (Nakayama et al. 1989). All vertebrate animals have two eyes, and some degree of binocular overlap is present even in animals with laterally located eyes (Fig. 2). However, the function of this binocular overlap

Binocular Disparity, Fig. 2 Diagrams of visual fields of humans and three bird species with the eyes at rest (with the bill or the nose facing forward). Pigeon and American

kestrel have laterally located eyes, whereas tawny owl has frontally located eyes (The avian visual fields are adapted from Martin (1994))

and its involvement in depth perception remains a subject of a lively debate, particularly in birds. Although some authors assert that avian binocular field produces stereoscopic depth perception, just as it does in primates (e.g., Nieder 2003), others argue that binocular disparity in avian vision is used primarily for in control of a beak placement and during visual inspection of items held in the beak (Martin 2009). Instead, depth perception in birds is proposed to rely on motion parallax produced by repetitive head movements (Kral 2003). The relatively large binocular field of owls (Fig. 2) is argued to be a byproduct of enlarged eyes and elaborate outer ears that prevent lateral placement of the eyes, an argument supported by a much smaller binocular field found in other birds of prey (Martin 2009). Unfortunately, global stereopsis (a process involving processing and comparison over a large portion of retina) has been convincingly demonstrated in only one bird species, barn owl (van der Willigen 2011), leaving the argument unresolved. In contrast, motion parallax has been shown to produce reliable depth perception in both humans and nonhuman animals (Kral 2003).

Although many insects have two or more eyes, their eyes are immobile and have a fixed focus; thus, most insects are unlikely to be able to use binocular disparity for depth perception and must rely on other cues such as motion parallax (Kral 2003). Relatedly, a few insects with a clearly established stereopsis appear to use it in a much more limited fashion than humans (e.g., for estimating distance to prey but not its size; Nityananda et al. 2016).

Conclusion

Binocular disparity in humans is an undoubtedly important cue aiding depth perception; anecdotal reports from the patients who underwent a successful vision recovery emphasize a dramatic improvement in their ability to perceive depth and to detect object boundaries (Ponce and Born 2008). In contrast, the evidence for extensive use of binocular disparity in depth perception in nonhuman animals is limited, with some authors

suggesting that monocular depth cues such as motion parallax may play a more important role, even in species with a considerable binocular overlap (Kral 2003; Martin 2009).

Definition

In biology, functions are attributed to the traits, behaviors, and parts of living things. A thing's function can refer to its purpose, a benefit it confers on an organism, or the causal role it contributes to a more complex system capacity.

Introduction

Biologists attribute functions to a diversity of natural phenomena, from chemical and cellular processes to the organs, traits, and behavior of organisms. It is common for them to say, for example, that the koala's pouch has the function of protecting its young, that the function of the bee dance is to direct other bees to pollen, or that chlorophyll in plants functions to absorb light and convert it into energy. Yet the term "function" is ambiguous, carrying importantly different meanings and occupying distinct explanatory projects in the biological sciences. This entry will introduce two characteristic features of biological functions, then overview three dominant analyses, each of which targets a distinct sense in which functions are conceptualized in the biosciences.

Functions, Teleology, and Normativity

What do biologists mean by “function”? In its most basic sense, “function” can simply refer to an effect something produces (Hardcastle 2002). For example, when geneticists say that amino acids function to catalyze RNA transcription, they just mean that RNA transcription is an effect brought about by amino acids. In some cases, however, when biologists assign functions, they seem to be saying something more.

Functions are commonly associated with two qualities. The first is purposiveness or “teleology”: functional ascriptions seem to tell us why something exists (Neander 1991). A koala’s pouch is for protecting its young, and chlorophyll’s purpose in plants is to transform light into energy. The second is *normativity*: a thing’s function often determines the standards by which it operates. Often biologists wish to say that, even when something fails to do something, it nonetheless *should* have. A single plant that does not produce chlorophyll *fails* to fulfill its function, and so is in a state of *dysfunction*.

The teleological feature functions has, in particular, provoked controversy and consternation (Neander 1991). It is easily accommodated in the case of artifacts, where we can articulate what something it is supposed to do by referencing human goals. The function of a microwave, for example, is to heat food because its inventor designed it for this use. In biology, however, the goal is to define function naturalistically, without presupposing the existence of a human, or supernatural, designer.

This has led some sceptics to suggest that functions do not belong in science (Davies 2003). This stance, however, sits uneasily with the ubiquitous and explanatorily powerful use of functional explanation in biology (Garson 2016). Analyses of biological function thus tend to either provide a naturalistic interpretation of teleology or else define function in a way that carries no commitment to it.

Causal Role Functions

The Causal Role analysis defines biological function in non-teleological terms. The motivation

behind this approach is not merely the perceived impossibility of naturalizing teleology, but a need to accommodate a widespread and non-purposive sense of function in biology (Cummins 1975; Hardcastle 2002). In many contexts, biologists are less concerned with explaining why an entity or trait exists than they are in analyzing the causal role it plays in a biological system (Cummins 1975; Amundson and Lauder 1994).

Briefly put, a causal role (CR) function is the output a system’s component produces that contributes to a system-level capacity (Cummins 1975). Take, for example, the function of the heart. The heart is a subcomponent of the cardiovascular system, which circulates oxygen, nutrients and hormones throughout the body. Within this complex system, the heart contributes to circulation by pumping blood. The CR analysis thus says that the function of hearts is to pump blood.

However, referring to *the* function of hearts is slightly misleading. A component’s CR function is always assigned relative to a system capacity that biologists are interested in (Hardcastle 2002). As complex systems possess a multitude of capacities, a component can be subject to more than one kind of functional analysis. Biologists can provide a functional analysis of a heart’s blood pumping, or they might instead be interested in analyzing the beating noise it makes, its size, or its weight. A system component can be assigned several functions, depending on the interests of researchers.

The CR account is pragmatic in spirit and places few limitations on what natural phenomena biologists can subject to functional analysis. However, it faces two key criticisms.

First, its neglect of teleology means it cannot distinguish between a function and a “fortuitous effect” (Neander 1991). In the realm of artifacts, we think that a vase can be used as a paperweight or a pen-holder, but its *proper* function is to hold flowers. Similarly, goes the intuition, a heart produces a range of effects which are not its proper function. The heart’s beating noise, for example, helps doctors diagnose cardiac pathology, but the heart’s function is not to make noises.

Second, the CR account struggles to accommodate the normativity of functions (Neander 1991). The kind of functional analysis that the

CR account generates describes what a system's component does is, as opposed to what is ought to do. A consequence of this is that biologists cannot say that a heart in cardiac arrest is malfunctioning; rather, it merely lacks the function of pumping blood, in much the same way that it lacks the function of photosynthesizing light or deterring nocturnal predators.

Selected Effect Functions

The Selected Effect (SE) theory aims to naturalize teleology (Millikan 1984; Neander 1991). Recall that functions are teleological when they tell us what something is for: hearts are for pumping blood; chlorophyll is for photosynthesis; etc. According to the SE theory, a thing's function *qua* purpose is determined by facts about its causal history. While in the case of artifacts, the relevant causal history concerns the decisions of a designer; in the case of biological entities, the designer is supplanted by Darwinian processes of natural selection.

SE functions are borne by traits that are *adaptations* – traits that organisms possess because they have given their ancestors a survival advantage. A trait's SE function is whichever of its effects is responsible for this advantage. For example, zebra stripes are thought to deter disease-carrying flies. Some biologists hypothesize that fly-deterrence is what led the striped phenotype to be reproduced over time: historically, zebras with stripes survived to leave more offspring than those without. If this hypothesis is correct, zebra stripes are an adaptation, and their function is to deter flies.

The historical constraint allows the SE analysis to distinguish between functions and accidental benefits (Griffiths 1993). Let's say that as well as their fly-deterrence effect, stripes also camouflage zebras from predators. On the CR account, both effects could be considered a function of the stripes. The SE analysis, in contrast, says that insofar as stripes were only selected because they deter flies, the fly-deterrent effect is their function, and camouflage is merely a "fortuitous effect."

This constraint also enables the SE analysis to deal with normativity (Griffiths 1993). A traits'

SE function is not simply one of its current causal capacities, but the one that has produced fitness benefits for members of its ancestral lineage (Garson 2016). This means that an organismic trait can have a function even in cases where it fails to perform it. Thus, we can say that a heart in cardiac arrest malfunctions because it fails to pump blood because pumping blood is the effect for which ancestral hearts were selected.

However, the SE analysis has a more limited scope than the CR account. Exactly how limited depends on how common adaptations are, and there is disagreement over this (Godfrey-Smith 2001). Nevertheless, there are other kinds of traits that biologists wish to subject to functional analysis, including vestiges (traits that are no longer an adaptation), spandrels (traits that were never an adaptation), and non-heritable traits of sterile animals (Hardcastle 2002). Finally, determining a trait's selection history, or whether it was selected at all, can also be very difficult, and for this reason, the SE analysis has been considered over-demanding (Garson 2016).

Fitness-Contribution Functions

The practical problems of studying selection history aside, biologists are often interested in the current fitness of a trait, or the likelihood it will be selected, rather than the selective regime that caused it to be reproduced (Bigelow and Pargetter 1987). While the fitness-contribution (FC) theory defines biological function using the conceptual resources of evolutionary theory, it is forward-looking: the function of a trait is the effect it contributes – or is disposed to contribute – to organismic fitness, regardless of the trait's causal origin (Bigelow and Pargetter 1987).

According to the simplest version of the theory, a trait has a FC function if it is *adaptive*: that is, when it raises the average fitness of organisms who possess it, when compared with those that do not. Take, for example, Darwin's dark peppered moth, which proliferated in polluted urban environments. The moth prevailed because its color, in this context, was adaptive: it enabled it to hide from predators. The FC function of the darker phenotype trait is thus to camouflage

moths, because camouflage increases the likelihood that it will survive and reproduce more than moths with a lighter-colored phenotype.

What this example illustrates, however, is that a trait's fitness is environment-dependent. A single trait can have a high average fitness value under one set of environmental conditions, and a low average fitness value under another. While a dark-colored phenotype aided the survival of peppered moths in polluted cities, it was a likely target for predators in the countryside, where lighter moths proliferated. Environment-dependence makes function-attributions unstable, with traits having different functions depending on time and place (Garson 2016).

The Propensity Theory is a version of the FC theory that tries to deal with this by specifying that a trait's function is whatever fitness advantage it is *disposed* to confer on an organism in its "natural habitat" (Bigelow and Pargetter 1987). This means that a trait can in principle have a stable function across environments that are hostile or unfavorable. The task of defining a "natural habitat," however, is unclear and unsettled. Indeed, if the natural habitat is simply the environment in which the trait evolved, then biologists can no longer bracket the trait's history, a key reason for preferring it over the SE account (Garson 2016).

Conclusion

The foregoing analyses can agree, in principle, on what function something has. Hearts can have the function of pumping blood because this effect contributes to circulation (CR), is the product of natural selection processes (SE), or increases the fitness of organisms who possess them (FC).

Even in cases where they agree, however, the three senses of function perform an importantly different explanatory purpose (Godfrey-Smith 1993). The SE function explains why a trait is there, the CR sense of function explains how a component part contributes to a systemic capacity, and the FC explains how a trait contributes to an organism's fitness in a contemporary environment.

The fact that these three senses of biological function are associated with distinct and fecund explanatory projects makes function pluralism,

the position that there is more than one legitimate concept of function within biology, a plausible stance (Godfrey-Smith 1993).

Definitions

The development of human gender identity may be influenced by organizational effects of prenatal hormones. This includes physical and neural development. Digit ratio (or 2D:4D) is a proxy of fetal hormones that correlates negatively with prenatal testosterone and positively with prenatal estrogen. Studies investigating associations between 2D:4D and sex-dependent traits suggest that in addition to genetics, prenatal hormones contribute to the determination of gender.

Introduction

At birth, humans are typically assigned to their biological sex (male or female) on the basis of their genitalia. But there is evidence from fetal studies that the sexual differentiation of the body occurs before the sexual differentiation of the brain (Swaab 2007; Bao and Swaab 2011). This gives the opportunity for considerable plasticity with regard to the social roles that are considered appropriate for males and females. These roles vary across societies such that it is appropriate to refer to the sexes as “male” and “female,” but to their culturally influenced gender roles as “masculine” and “feminine.” Here, we address the problem of the biological core of gender roles. Does it exist, and if so how important is it in influencing behaviors that we consider to be “masculine” and “feminine”? These questions are important in both a Darwinian and a social-cultural context. Our direct fitness is measured in number of offspring. It is in part dependent on the function of our gonads. However, if there is a mismatch between gonadal development and the sexual differentiation of the brain, then the result may be a reduction in fitness. Such transgendered individuals may be fairly common. In a large ($n > 255,000$) online study (The BBC internet study; Reimers 2007), 47.3% of participants gave their gender as female and 52.7% as male. In answer to the question “*Regardless of your biological sex, what sex do you feel?*”, a total of 4.0% of “males” selected “female” and 4.3% of “females” selected “male.” Clearly, there may be

both sociocultural and biological factors at work here. We briefly consider the former before discussing the latter in more detail.

Gender and Social Influences

One influential model regarding the social etiology of gender is the *gender schema theory* (Bem 1981). This envisages gender-associated information is transmitted by schemata or networks of information. Bem maintained that there are individual differences in the degree to which people hold these gender schemata. These differences can be seen by the degree to which individuals are sex-typed.

Another important theory which considers social factors in the determination of gender is that of *social role theory* (Eagly 1997). This suggests that the labor division between men and women is a major determinant of gender differences. Thus, men and women are expected to fulfill different roles in the work force and then assumed to exemplify the characteristics of those roles. Work force roles are strongly related to interest in things (stronger in men) and in people (stronger in women) and these preferences are remarkably robust across cultures (Lippa 1998). Such patterns could be construed to support both a social and a biological influence on gender.

The concepts of masculinity and femininity and their marked plasticity can also be applied to societies (Hofstede 1991). Thus, a society can be called masculine when emotional gender roles are distinct. Men are assumed to be tough and preoccupied by material success and women are supposed to be tender and concerned with the quality of life. In contrast, a feminine society is one in which the emotional roles overlap such that both men and women are tender and concerned with the quality of life. The *Masculinity Index* (MAS) is a society-measure of preference for achievement, heroism, assertiveness, and material rewards for success – independent of economic development. Countries such as Slovakia (MAS = 110), Japan (MAS = 95), and Hungary (MAS = 88) have high masculinity scores, while Sweden (MAS = 8), Norway (MAS = 8), and the

Netherlands (MAS = 14) lie at the opposite end of the masculinity spectrum (Hofstede 1991). It is to be emphasized that MAS scores are independent of economic indices such as gross domestic product. Clearly, there are factors other than national wealth at work here.

Gender and Biology

The plasticity of gender patterns is remarkable. However, this does not preclude a substantial biological effect on gender. Swaab and colleagues (Bao and Swaab 2011; Swaab 2004, 2007; Swaab and Garcia-Falgueras 2009) have discussed the interdependent biological processes involved in the formation of the reproductive system and in the subsequent sexual differentiation of the brain. In boys, the penis, prostate, and scrotum are formed during fetal weeks 6–12. This begins under the influence of the Y-linked SRY gene (Berta et al. 1990) and continues with the production of testosterone and dihydrotestosterone. In girls, the development of the sexual organs primarily depends on an absence of large amounts of androgen. The masculinization/feminization of the nervous system and behavior occurs later in gestation and results predominantly from the permanent “organizing” effects of testosterone in the second trimester of development. Brain areas that show sex differences that relate to gender include the bed nucleus of the stria terminalis, the third interstitial nucleus of the anterior hypothalamus, and the shape of the corpus callosum (Saraswat et al. 2015). At puberty, the brain circuits that have been organized prenatally are activated by sex steroids (hence the term activational effects). In addition to this large effect of prenatal androgen, there are also genetic and epigenetic influences on the sexual differentiation of the brain during the second trimester (McCarthy et al. 2009). Associated with the sexual differentiation of the brain are medical conditions that are more common in females (e.g., anorexia nervosa, bulimia, and Alzheimer’s disease) or in males (autism, attention-deficit hyperactivity disorder [ADHD], and stuttering).

Prenatal androgens, such as testosterone, have also been implicated in the etiology of transgender

identity. Transgender individuals have a gender identity that differs from their assigned sex, and in this regard, there is a preponderance of males over females (Bao and Swaab 2011). Some transgender individuals seek medical intervention to transition from one sex to another and are referred to as transsexuals. As with transgender individuals, male-to-female transsexuals (MTF) are more common than female-to-male (FTM) transsexuals (Bao and Swaab 2011). Transgender identity is not related in any substantial way to sexual orientation, suggesting different etiological pathways (Pauly 1998). Twin studies have provided evidence of a strong genetic influence on transgender identity (e.g., Heylens et al. 2012), and there are a number of studies indicating MTF individuals show atypical cerebral networks in both gray and white matter structures (reviewed by Saraswat et al. 2015). Overall, the characteristics of transgender individuals suggest a behavioral trait that is fixed early in development and is not substantially influenced by social factors.

The more nuanced effects of prenatal androgens on gender may be seen in studies using morphological proxies of fetal hormones and in assays of fetal hormones. With regard to morphological proxies, digit ratio (2D:4D) – the relative lengths of the second and fourth digits – is the most commonly used trait. The 2D:4D ratio is influenced by a balance of fetal testosterone to estrogen such that 4D length is increased relative to 2D length when prenatal testosterone concentration is high relative to prenatal estrogen. Therefore males, with their high levels of prenatal testosterone, have longer fourth digits relative to second than do females (male 2D:4D < female 2D:4D; Manning et al. 2004). Much of the sex-dependent variation in 2D:4D appears to be determined in a rather narrow window of development towards the end of the first trimester (Manning 2002; Szwed et al. 2017). With regard to fetal sex steroids, data have been obtained from hormonal assays of routine amniocentesis tests performed during the second trimester of development (Baron-Cohen et al. 2004).

Digit ratio studies have reported many associations between 2D:4D and sex-dependent traits. They include links between low 2D:4D (high

prenatal testosterone relative to estrogen) in autism (Manning et al. 2001) and ADHD (Martel et al. 2008), and high 2D:4D (low prenatal testosterone relative to estrogen) in schizophrenia (Qian et al. 2016). Studies of 2D:4D in transsexuals has yielded mixed results. In some reports MTF individuals have higher (more feminized) 2D:4D than normative male controls but no effect in FTM individuals (e.g., Schneider et al. 2006). In contrast, FTM transsexuals have been reported to have lower 2D:4D than controls, but no effect in MTF individuals (e.g., Wallien et al. 2008). These discrepancies may, at least in part, result from differences in measuring finger lengths (see Leinung and Wu 2017 for discussion).

With regard to social role theory, 2D:4D and other testosterone-dependent traits have been linked to the labor division between men and women. Manning et al. (2010) have reported data from the BBC Internet study, showing that the proportion of women (PW) across occupations is moderated by two morphological correlates of testosterone (2D:4D and height) and a systemizing–empathizing score [SQ–EQ] – a putative behavioral correlate of prenatal testosterone. Systemizing is the drive to analyze systems or construct systems while empathizing measures a person’s ability to understand thoughts and feelings of others (Baron-Cohen et al. 2004). PW varied per occupation from 17% in engineering and research & development to 94% for homemakers. Tall women with low 2D:4D and high SQ–EQ scores tended to be found in low PW (male-dominated) occupations. Focusing on individual occupational preferences in the BBC study, Manning et al. (2017) found that low (masculinized) 2D:4D was related to preferences in heterosexual men and women for “male-type” occupations such as car mechanic, builder, and carpenter. Thus, we can see that a proxy for high prenatal testosterone (relative to estrogen) may interact with the pressures postulated by social role theory. The result may be that prenatally masculinized women are attracted to “male-type” occupations.

Mean 2D:4D and the magnitude of sex differences in 2D:4D vary across nations. Such variation may correlate with between-nation variation in gender-related traits. For example, high

national 2D:4D has been shown to correlate with high national scores for uncertainty avoidance and neuroticism (Manning and Fink 2011). Interestingly, countries that show the smallest sex differences in national 2D:4D also have low scores for gender inequality (Manning et al. 2014). This finding may map on to the national Masculinity Index (MAS). Further work is necessary to clarify this relationship.

Studies of 2D:4D and gender-related traits may overlap with reports concerning prenatal sex hormones and behaviors such as autistic traits and “tomboy” play patterns. With regard to the former, children with autism tend to avoid eye contact. A tendency for high levels of eye contact is associated with low concentrations of fetal testosterone (Lutchmaya et al. 2002) and high 2D:4D (Saenz and Alexander 2013). With regard to the latter, high levels of “male-typical” play in boys and girls are related to high concentrations of fetal testosterone (Auyeung et al. 2009). “Tomboyism,” a tendency for girls to play with boys and boy’s toys, is also associated with low (masculinized) 2D:4D.

Conclusion

Gender is highly variable across individuals and across societies. These patterns speak to the notion that factors such as occupational roles are the major determinants of gender. However, there is much evidence that prenatal influences of both genes and sex steroid hormones contribute to the determination of gender. Such biological influences provide the substrate upon which social factors are built upon. In that sense they may provide the key to what we perceive as gender.

Biosemiotics

Donald Favareau
National University of Singapore,
Singapore, Singapore

Definition

The term *biosemiotics* derives from the Greek root *bios* (“life”) *semeion* (“sign”) and suffix *-ika* (“study of”). Biosemiotics is thus the study of sign processing both within and between living systems.

History and Overview

The contemporary interdisciplinary research agenda of Biosemiotics has its roots in the pioneering work done by the linguist Thomas A. Sebeok (1920–2001) in bringing biologists and semioticians together to develop more fine-grained understandings about animal communication practices – and, in particular, about how those practices might underlie the evolution of human language use (Sebeok 1990, 2001).

Sebeok initially christened his interdisciplinary research project *zoösemiotics* – “a discipline within which the science of signs intersects with ethology, devoted to the scientific study of signaling behaviour in and across animal species” (Sebeok 1969).

However, as the number of researchers from various fields of study (including zoology, neuroscience, comparative psychology, and even molecular biology) began to grow, the focus of this interdisciplinary enterprise likewise expanded to include the study of signaling processes within organisms, as well as between them. Accordingly, by the 1990s, researchers in this still-developing area of study were using the term *biosemiotics* to denote the shared research agenda of exploring how signaling processes both internal to, and exchanged between, organisms could be understood as the products of evolutionary adaptation and change (Hoffmeyer 2009).

Much of the early work done in this project sought to build upon the insights of experimental physiologist Jakob von Uexküll (1864–1944) as well as the logician Charles Sanders Peirce (1839–1914) in the analysis of animal communication systems and display behavior (Favareau 2006). From von Uexküll, whom Nobel Prize winners Konrad Lorenz and Nikolaas Tinbergen called “the father of animal behavior study,” Sebeok and his colleagues incorporated the notions of species-specific sensory worlds and the imprinting of meaning upon stimuli via sensation-action feedback cycles (von Uexküll’s *umwelt* and *functional circle* ideas, respectively), while many of von Uexküll’s other pioneering ideas were simultaneously being

developed in the sciences of cybernetic feedback control and neural networking (von Uexküll 2010; Kull 2003).

Developing a “scientific logic of sign relations” was the lifework of mathematician, logician, and philosopher Charles Sanders Peirce, and many biosemioticians employ Peirce’s nested hierarchy of *iconic*, *indexical*, and *symbolic* relations (Peirce 2010) in their analyses of, respectively, primary sensory experience, object-action association patterns, and higher-level lawful behavior arising from the species-specific ways in which such association patterns are systematically organized. Most notably, Peirce’s sign logic is used by neuroscientist and biological anthropologist Terrence Deacon in his 1997 book *The Symbolic Species: The Co-Evolution of Language and the Brain*, to argue for a view of human language evolution which has its roots in earlier forms of animal sign processes, but which becomes distinctive with the uniquely human ability to create signs that signify not just real-world events and objects, but also signs that signify other signs (Deacon 1997).

With the death of Thomas Sebeok in 2001, the center of gravity for the biosemiotics project shifted to the University of Copenhagen under the auspices of biochemist and molecular biologist Jesper Hoffmeyer and the philosopher of science Claus Emmeche who, along with cybnetician Søren Brier, and the Estonian botanist and theoretical biologist Kalevi Kull, established the Biosemiotics Group at the University of Copenhagen in the early 1990s and who together hosted the first international Biosemiotics conference in 2001. That conference has been held annually, in various cities in Europe and in North America, every year since then, and the field, while still early in its development, now has its own international society, peer-reviewed journal, and book series.

Conclusion

With evolutionary psychology, biosemiotics seeks to productively bring together researchers in the life sciences, the social sciences, and the

humanities in order to develop a naturalistic understanding of the use, structure, biology, and evolution of sign processing in living systems (Kull et al. 2009).

Definition

Biosociology is an umbrella term for the contributing research areas (including but not limited to neurosociology, evolutionary sociology, and social science genomics) that studies the role of evolved biological factors (genetic, neural, hormonal, etc.) in different dimensions of social behavior, as well as being concerned with the biosocial mechanisms of social phenomena and processes at both micro and macro levels.

Introduction

Biosociology began to develop during the 1990s, growing out of findings from initiatives such as the Decade of the Brain and the Human Genome Project. Its development was significantly influenced by other disciplines (e.g., social and cultural neurosciences, evolutionary psychology, behavioral genetics, and other related science subjects), whose findings – intentionally or not – fell within the domain of traditional sociology. Partly as a response to that, social scientists have tried to incorporate biological variables into sociological conceptions combining data generated in the aforementioned research areas with those generated in sociology, while maintaining disciplinary boundaries.

Evolutionary Sociology: Applying Evolutionary Theory to Sociology

Some sociologists consider observed behavioral and other human traits as evolutionarily acquired adaptations with historic utility, but which may be of lesser value in a modern social context. Typical aspects of interest to evolutionary sociology are social phenomena and processes at the macro level, where they considered as institutionalized forms of certain behavioral adaptations. Thus, patrilineal inheritance of property as a norm in certain countries, restrictions on female social mobility, gender differences in earning potential, and other aspects of patriarchal regimes are treated as social mechanisms that facilitate maintenance of male social dominance and, from an evolutionary perspective, that allow males control over the behavior of reproductive-age females to maximize confidence in paternity (Hopcroft 2015). Among other themes, sociologists are also interested in the development of human emotionality (including its contribution to formation and maintenance of the strong social ties that allowed human ancestors to cooperate for protection against predators (Turner 2014)), systems of representation of high or low status within social groups (essentially a recapitulation of those observed in nonhuman primate society), and

underlying neurohormonal mechanisms (Mazur 2015). The major recent findings of evolutionary sociology are reflected in *The Oxford Handbook of Evolution, Biology, and Society* (Hopcroft 2018) and in *The New Evolutionary Sociology: Recent and Revitalized Theoretical and Methodological Approaches* (Turner and Machalek 2018).

In Search of Neurobiological Mechanisms of Sociality

Neurosociology centers on the association between human brain activity and micro and macro level social phenomena and processes, its role in their formation, and a reciprocal effect. The main subject of interest to neurosociology is the neurobiological mechanisms underlying social behavior in members of different social groups, taking into account variation in their position within the social structure, cultural values, political ideologies, etc. Sociologists working in this area attempt to incorporate experimental findings from neuroscience into traditional sociological concepts, as well as (albeit much less frequently) conducting their own research using neuroscientific methods and meta-analysis. Among others, current research interests focus on issues of social identity and interactions, instrumental rationality, social solidarity, mechanisms of social learning, and the neural correlates of persistent inequality. Publications such as the *Handbook on Neurosociology* (Franks and Turner 2013) and *Neurosociology: The Nexus between Neuroscience and Social Psychology* (Franks 2010) have significantly supported formal acceptance of this research area.

Genetic Factors in Social Behavior and Development of Social Science Genomics

In accordance with recent scientific findings, some social scientists estimate the weight of genetic factors – along with the social conditions under which their influence is manifested – in

contributing to sexual behavior, gender and racial differences, academic success, cognitive abilities, socioeconomic status, levels of well-being and happiness, deviant behavior, sex, and gender role behavior, etc. Such studies commonly use genetic information available in selected preexisting databases, including those maintained by the National Longitudinal Study of Adolescent Health, the National Survey of Midlife Development in the USA, and the Middle-Aged Danish Twin Survey. Polygenetic score analysis is now considered a promising methodology facilitating estimation of genetic predisposition to human traits of interest to sociologists. Thus, attempts to take into account genetic factors in the consideration of social behavior contribute to the development of social science genomics potentially within sociology (Freese 2018).

Fluid and Nascent Emerging Boundaries Between Biosociological Approaches

Boundaries between different biosociological approaches are not fixed. Thus, sociologists working within evolutionary sociology and neurosociology may investigate overlapping subject areas. For example, they may study features of neural activity associated with or affecting social behavior (primarily a focus of neurosociology) as a result of adaptive behavioral processes arising from evolutionary development (primarily a focus of evolutionary sociology). In such a case, some sociologists employ the term “evolutionary neurosociology” (e.g., when studying the role of emotions in the formation and representation of social rank differences (TenHouten 2017)).

There are also biosociological works which did not fit into any of those research areas. For example, some sociologists emphasize neurophysiological measures of social inequality (stress, health, etc.), while others emphasize the concept of transformation of social identity under the influence of the information obtained via DNA testing. However, all sociologists aim to construct more balanced (i.e., incorporating more equal weighting of biological and social factors) and up-to-date sociological concepts and theories.

Formally, social scientists, whose researches falling under the rubrics of biosociology, are consolidated into Evolution, Biology, and Society Section of the American Sociological Association (section was founded in 2007). Since 2016, the specialized Frontiers journal *Evolutionary Sociology and Biosociology* has also been published.

Conclusion

Results deriving from biosociology research demonstrate that the social behavior of modern humans is at least partly determined by stable forms of behavioral adaptations (evolutionary sociology), explained by human brain structure (neurosociology), and probabilistically determined by genetic factors (social science genomics). Despite this progress, however, the development of biosociology remains in its infancy. Perspective depends on social scientists’ level of knowledge regarding biological sciences, as well as on the willingness to adapt current sociological methodology and theory. Many sociologists attempting to develop current biosociological approaches have faced prejudice from colleagues who fear that sociology will be reduced to other disciplines, or that new approaches may encourage racism, sexism, or other forms of social discrimination. Such biophobia is partially rooted in the history of sociology, connected with E. Durkheim’s concept regarding the sufficiency of social factors to explain social phenomena, as well as with false ideological connotations accompanying the development of Social Darwinism. Given current knowledge regarding the determinants of human nature, equating the sociological with the non-biological is a significant obstacle to development of sociology as a reputable scientific discipline.

Biosocial model of social status; Biosociology of social dominance hierarchy; Biosociology of social status hierarchy

Definition

The Biosociology of Dominance and Deference is a biology-inspired sociological approach analyzing evolutionarily evolved neurobiological mechanisms of different dimensions of human social ranking in terms of power, influence, prestige, and access to different resources which contribute to the development of traditional sociological conceptions on social stratification and social inequality.

Introduction

Dominance hierarchy is currently widely recognized as universal in the animal kingdom. It is not coincidental that this problem came to the attention of researchers from different disciplines, including neuroscience, social and cultural neuroscience, and evolutionary psychology. As a result, in the last decades many findings concerning the biological nature of hierarchical relations among animals (including humans) were obtained that are potentially helpful for the sociological understanding of human interactions based on social rankings.

Evolved Adaptations to Hierarchical Social Relations

In the perspective of evolutionary sociology, stable forms of behavioral and other traits associated with producing and maintaining hierarchical social relations are considered as evolved adaptations that promote our ancestors' survival. Adaptations to hierarchical social relations have become part of human biological nature (including structure of the brain). Individuals, who possessed ability to navigate in socially differentiated society, correctly identified rank signals, and behaved in accordance with their own position in the social hierarchy, survived more frequently in comparison with those who lacked such abilities.

Emotions (Ten Houten 2017), communication signs (Mazur 2005, 2015), and sexual behavior

strategies (Hopcroft 2016) as such adaptations have recently been studied from the perspective of sociology. Thus, it has been demonstrated that secondary emotions of “pride” (formed from angry and joy) and “shame” (which comprises fear and sadness) appear as adaptive reactions to high and low status in social dominance hierarchy. Pride allows a person to achieve and demonstrate his/her dominant position, while shame provides subdominants a means to express a deferent low-status position and avoid punishment, negative evaluation, or the help to receive necessary resources. As a result, an ability to transmit, express, and recognize emotions as a signal about dominant or subordinate status is useful for everyone, regardless of place in the social hierarchy (Ten Houten 2017).

Mazur (2005, 2015) divides all status signals according to constant and controllable signs. The first are almost unchangeable (e.g., sex, ethnic markers, age, reputation), while the last can change for representation of domination or submission in accord with the actual situation and human purposes (e.g., gestures, tone of voice, semantic content, items of dress, and accessories).

The differences in male and female behavioral strategies reflect the differences in the adaptive problems that they solved – to increase the probability of more offspring, invest only in own offspring, and get support from men during the period of childbearing and raising children (Hopcroft 2016). Such biological predispositions are expressed in the deference of young females to males (but not other young females), and the absence of the reverse (only deference of males to other males is observed), which are supposed to help females guarantee their support, material and otherwise, from males. On the other hand, such inherently discriminatory attitudes of men at puberty toward young women in many cultures increases men’s social status, which is favorable for finding mates; in accord with that is the finding in recent studies (e.g., Hopcroft 2015) of the association between the socioeconomic status of males, but not females, and the number of offspring. This also explains the status parity between adult men and women of

nonreproductive age or even higher status (Hopcroft 2009). A greater biological determinacy of female behavior toward children (childbearing, lactation, nursing), as well as existing hormonal differences between the sexes make women more attuned to children’s upbringing; this is one of the reasons why the majority of positions of power, privilege, and influence in society belong to men (Huber 2007).

Biosocial Mechanisms of Social Dominance

In biosociological studies of dominance, findings concerning the homogeneity of the basic biological mechanisms among all social primates are taken as a starting point. Thus, the neurohormonal mechanisms of the human system of reporting about high or low status are considered the same as for nonhuman primates, as are the basic signals themselves (apart from language).

As a neurohormonal mechanism, the influence of testosterone on the dominant orientated behavior as well as the reciprocal effect are tested in the context of differently mediated social factors, including anticipation of a contest, the perceived importance of the outcome, the outcome of the contest, and some others (Mazur 2005, 2015). Along with the testosterone factor relevant to the biosocial model of dominance and deference, the associations between the neurophysiology of stress and high/low human status are discussed, in particular, the biosocial mechanisms whereby high ranking persons experience stress less frequently and can intentionally impose stress on those below them on the hierarchy to maintain their dominant position (Mazur 2015). Stress, together with other neurophysiological differences reflected in human health, is now studied as a new dimension of social stratification (Groosby et al. 2018). Finally, the first attempts have been made to incorporate genetic factors in considering traditional sociological issues; these concern the intergenerational transmission of socioeconomic status in terms of educational attainment (Liu 2018).

Conclusion

Striving for high status and material well-being is rooted in human biology although it is culturally elaborated. However, no matter how sophisticated this refinement is, the biological nature of people formed in the process of long evolution has not disappeared. Understanding it allows (bio)sociologists to analyze the underlying causes of social behavior associated with the social dominance hierarchy that were formed as a result of the interaction between biological factors and the environment. Such research complements current sociological conceptions on social status and social inequality by biological factors and, potentially, makes them more complete and exact.

Biparental Care

Lance Workman
University of South Wales, Pontypridd,

Synonyms

[Mutual parental investment](#)

Definition

Biparental care is the situation whereby male and female parents share responsibility for raising their mutual offspring.

Introduction

Across the animal kingdom, patterns of parental care vary from no care through uniparental female

or male care to biparental care where both parents invest in the offspring. Among the vertebrates, biparental care is highest in avian species where it is estimated to be the case for 81% of species (Cockburn 2006) and lowest in mammals where estimates are below 10% (Kleiman 1977). This observed variation raises the question as to what are the evolutionary driving forces for the emergence of biparental care.

The Biparental Care Hypothesis and the Evolution of Monogamy

According to the biparental care hypothesis, this pattern of exclusive cooperation in care of mutual offspring evolves when each parent achieves higher reproductive success than either can through polygamy (Wittenberger and Tilson 1980). Hence biparental care is seen as a driving force for monogamy. Support for this hypothesis has come from a number of studies involving parental removal in species of birds, fish, and amphibians (see, e.g., Møller 2000; Tumulty et al. 2014). In such studies the male of the pair is generally removed leading to a reduction in offspring survival. This has been taken as evidence that, if one parent were to perish, the remaining widowed parent would not be able to provide sufficient care for the offspring alone. The unusually high incidence of biparental care in birds is generally regarded to be a result of the extensive resource requirements for the development of flight-capable fledglings. Clearly outside of bats, this is not an issue for mammalian species.

This mammalian pattern of little or no male parental care is also the case for the majority of primate species. While some species of lesser apes such as the agile gibbon do engage in biparental care, among the great apes, male care of offspring is virtually nonexistent. In contrast, although human mating patterns vary across cultures, monogamy with biparental care is commonly observed (even in cultures where polygyny is accepted). Hence humans are, as a species, high in what Robert Trivers has described as “male parental investment” (MPI, Trivers 1972). This raises two important

questions: why is biparental care so common in our species, and what effect has high MPI had on human evolution?

Bipedalism and Biparental Care in Human Evolution

Over the last four million years, human ancestors have exhibited a rapid increase in brain volume accompanied by a narrowing of the pelvic girdle to enhance bipedal locomotion. These two, arguably conflicting, changes led to an increasingly large brain having to fit through an increasingly narrow pelvis. The solution to this problem was to give birth to a developmentally younger fetus. This, in turn, led to hominin babies being born at increasingly immature and dependent stages of development. Moreover, it also led to an increase in the length of infancy. According to the provisioning hypothesis, due to the dependency of human neonates, it paid human males to shift from polygynous mating patterns to pair-bonded ones which thereby boosted reproductive success for both parties (Lovejoy 1981). It also increased selection pressures for improved bipedal locomotion since this freeing up of the hands allowed hominins to gather and bring back a wide range of foods. Note that in this model of human evolution, bipedal locomotion and pair bonding are inextricably linked. Although the provisioning hypothesis has been criticized for being male centered, features of it are widely accepted as an explanation for the evolution of biparental care in our species. In particular, with the division of labor that human biparental care allows for (broadly speaking men hunt and women forage), the range of nutritional items increased for all in the proto-family unit. It may also be that the increase in meat in our ancestral diet allowed for the expansion of the human brain (the brain demands 20 times as much energy as muscle tissue and consists largely of protein). To some, the formation of biparental care and the resultant increase in protein and energy-rich foods available to the growing child were a watershed moment in human evolution (Wrangham 2009).

Biparental Care and Human Psychological Dispositions

Evolutionary psychologists consider that biparental care has helped to shape human psychological dispositions. Following the evolution of biparental care, the introduction of meat into the ancestral diet may be seen as a necessary precursor to an increase in brain size, but it was not sufficient. In addition to an appropriate change in diet, an increase in brain size (and the resultant increase in intelligence) can only arise if there are selective pressures for this development. An increase in MPI is known to have a number of effects on both male and female reproductive behaviors. Due to their increased effort in offspring production, males become more choosy about whom they will mate with, and females become more competitive over potential male partners (Stewart-Williams and Thomas 2013; Stewart-Williams 2017). This means that, once biparental care is established in a population, both sexes then demonstrate a degree of choosiness, and both exhibit a degree of same-sex competitiveness (it should be noted, however, that females are likely to remain the choosier sex due to maintaining a higher level of parental investment than males). Same-sex competitiveness and opposite-sex choosiness are the main components of sexual selection (i.e., the opposite sex does the “selecting” rather than the environment as in natural selection).

In 2000 American psychologist Geoffrey Miller began to champion the notion that, once biparental care had evolved, the main driving force for increasing brain size and intelligence became sexual rather than natural selection. Drawing on Darwin’s (1871) work on the relationship between sexual selection and the evolution of human abilities, he called this the mating mind hypothesis. Miller proposed that, with an increasingly dependent offspring being born into a challenging savannah environment, it paid both sexes to recombine their genes with caring and intelligent individuals (Miller 2000). Given that sexual selection can act more rapidly than natural selection, it can be argued that the emergence of biparental care was a major factor in driving both human intellectual and emotional abilities

toward the advanced levels we see today (Workman and Reader 2014).

Conclusion

Where biparental care is observed in the animal kingdom, it is seen as a driving force for monogamy. This also appears to be the case for our own species. For our hominin ancestors, the evolution of biparental care is likely to have had a profound effect on our behavior including increases both in choosiness in males and in levels of female/female competition. It may also have provided a driving force, through sexual selection, for expansion of human intelligence and cooperative behavior.

Bipedal Gait

► Bipedal Locomotion

Bipedal Locomotion

Olivia Jewell
SUNY New Paltz, New Paltz, NY, USA

Synonyms

Bipedal Gait; Bipedal Motion

Definition

The phenomenon of walking upright on two hind limbs, as opposed to using both forelimbs and hind limbs for running, climbing, etc.

Introduction

Bipedal motion is one of the features of modern humans that most drastically separates us from other primates and great apes. Several different theories as to how we developed bipedal motion relating to diet, terrain, and morphology have

developed and changed over the years as physical evidence has increased and refined the ways we think about hominin bipedalism. With the understanding that some theories have been discarded or severely changed since their debuts, presented here is a full analysis of each of the predominant theories of bipedal motion in humans, including those that have not been reconsidered in several years due to compromising evidence. Additionally, there are certain biological and physiological explanations for bipedal locomotion and how that anatomy compares to that of our ancestors and modern nonhuman primates.

One major assumption made by researchers is that adopting a bipedal form of locomotion was adaptive in such a way that it aided survival and carried on into modern human anatomy. The Miocene era, which was a time of dramatic climactic change around 4.4 million years ago, is the approximate time during which bipedalism is thought to have evolved (Hunt 1994). Each of the following theories cites the hypothesized environment during the Miocene era and why bipedal locomotion would have been adaptive for that environment at that time.

Geological as well as fossil evidence has indicated that the climate and environment in Africa were wetter and more lush than they are today. It is supposed that animals could have been living in an area that was relatively well covered by trees, being similar to a forest or woodland (Hunt 1994; Thorpe et al. 2007).

Since the Miocene era was a time of such change, some theorize that hominins would have begun moving from a more forested habitat, to a more open one. As they did so, they would need to develop a bipedal stance to see further, without the assistance of trees (Ravey 1976). A bipedal stance would have also assisted the animal in cooling itself when out in direct sunlight, especially since there would be less skin area coming into view of the sun while standing (Ruxton and Wilkinson 2011). It is also thought that these early hominins would have transported themselves bipedally in the trees before climbing down and continuing to be bipedal (O'Higgins and Elton 2007; Thorpe et al. 2007). Another theme in the theories of bipedalism is that

developing a bipedal gait would have freed up the arms for carrying things like tools or food (Brace 1962; Watson et al. 2007). Each of these ideas is examined in greater detail below.

Potential Origins for Bipedal Locomotion

The Miocene period was characterized by a particular group of hominin ancestors, the Australopithecines, and *Ardipithecus ramidus*. Both of these ancestors to the hominin lineage have left behind important evidence as to how they traveled, and both display lower-limb anatomy that would have likely supported bipedal motion (DeSilva 2009; Lovejoy and McCollum 2010).

Predator Avoidance

As hominins migrated towards open spaces, many may have become bipedal to cope with the wide surroundings and changes in feeding habits, especially for the smaller of these hominoids. Additionally, it has been suggested that as these animals are foraging through tall grasses and may be unable to see over them while in a quadrupedal position, the development of a bipedal stance would have aided in their ability to see threats. While this line of reasoning may not have produced bipedalism quickly, even short moments of bipedal posture may have been the difference between life and death for some of these smaller hominins (Ravey 1976).

Similar to this argument, Brace (1962) points out that Australopithecids, defending themselves from large carnivores, would have needed to use hand-held weapons and tools, since they lacked the large canines seen on other primates. Without the use of weapons, these early hominins would have been completely defenseless. Since it is clear that they survived, they must have done so by using weapons to defend themselves and developed an upright stance as a response to this (Brace 1962).

While increased viewing distance would have potentially been an immediate difference between life and death, observations of modern nonhuman primates show that they rarely engage in bipedal

forms of social display to resolve conflicts or to assist in vigilance over the social group. It has not been truly tested whether or not there would have been a significant increase in viewing distance for the australopithecines, by standing upright, and this would likely not have occurred often enough to substantiate evolving an entirely new method of locomotion (Hunt 1994).

Thermoregulation

When people walk, they use more energy and produce more heat. This heat can accumulate greatly especially on a fur-covered animal in direct sunlight (Queiroz do Amaral, Quieroz do Amaral 1996). An examination on energy usage by upright-walking hominins can provide evidence for later hair loss in hominins as we became bipedal. Ruxton and Wilkinson (2011) created a model to predict the average amount of energy humans use while walking outside in direct sunlight at different times of day. They compared results of the model between fur-covered and hairless hominins. Results indicated that fur-covered hominins would likely have been unable to walk long distances in direct sunlight, in habitats that would have looked the way Africa did. This assumes that the greatest source of heat comes from internal production from an animal using energy (Ruxton and Wilkinson 2011).

The main conclusion that these authors came to base on their analysis stated that it is unlikely that hominins developed bipedal motion *because* it would have been more energy efficient. The evidence for this is presented in the fact that walking on 2 ft produces more internal heat than merely standing, and would have made walking long distances incredibly difficult for fur-covered animals. This implies that hominins would have needed to evolve bipedal motion through other circumstances and then lose some of their hair coverage as a result (Ruxton and Wilkinson 2011). It is also hypothesized that there would have likely been a large amount of tree coverage around this time, in Africa, meaning that the thermoregulatory reasons for bipedalism likely would not have been relevant, based on the environment.

This would then cause selection for reduced hair coverage as a way to promote heat loss.

Evidence from human body parasites from around 3mya suggests that this may have been around the period when hominins were losing body hair. This is likely already one million years after hominins came definitively bipedal; however, this is a loose hypothesis (Ruxton and Wilkinson 2011). However, Queiroz do Amaral asks whether or not being hairless would have been more adaptive for regulating heat loss as hominins became bipedal, not after (1996). She suggests that loss of body hair would have occurred before or in conjunction with the evolution of bipedalism, not after bipedalism had already evolved. This is because the reduction in body hair could have compensated for the higher energy required to move bipedally, even in a potentially forested environment (Queiroz do Amaral, Quieroz do Amaral 1996).

While it may seem convincing that increased sunlight would have been an important motivator for bipedalism to occur, early Miocene habitats would have been much more covered than the environment in Africa is today. This means that while walking upright would have decreased the amount of sunlight and heat reaching an animal, there would not have been an intense need to do so because the amount of sunlight reaching the ground would already have been compromised by tree coverage. Essentially, the amount of heat reduced by standing upright in these conditions would have likely been so insignificant that adapting an entirely new form of transportation would have been unlikely and inefficient (Hunt 1994; Ruxton and Wilkinson 2011).

Arboreal Locomotion

Observations on the locomotor patterns of non-human apes indicate that the posture and gait of orangutans when walking across tree branches is different than that of other apes. Interestingly enough, orangutans appear to move through the trees in ways similar to that of modern humans moving across the ground (O'Higgins and Elton 2007; Thorpe et al. 2007). Orangutans could have developed this form of walking through branches since it appears to be safer, as they have the ability to grasp upper branches for balance. Thorpe et al. (2007) use this to later assert that one particular

early hominin, *Australopithecus afarensis*, could have been a biped at short distances.

Again, as the arboreal climate in Africa became less dense, primates had few options. It is hypothesized that arboreal bipedalism would have transferred effectively into terrestrial bipedalism, while other great apes, who were built for vertical motion in trees, would have more likely moved towards the knuckle-walking we see today in Gorillas and Chimps. This can be substantiated by certain physiological evidence found in the skeleton of modern humans. Evidence for cranial morphology that allow for the skull to sit right at the top of the spinal column in a vertical fashion suggests an upright posture, since humans have the ability to balance themselves above a central point. Lumbar and spine anatomy in modern non-human apes, they are unable to naturally balance themselves this way and therefore would struggle to walk bipedally. To adjust for this, they are forced to bend their knees and hips to achieve this balance. These features were likely not part of the anatomy of the last common ancestor that humans shared with these apes (Lovejoy and McCollum 2010). Therefore, the authors assert that the knuckle-walking we see in modern non-human primates was never a precursor to modern human bipedalism because of this necessary skeletal realignment (Thorpe et al. 2007). Other evidence provided by the skeletal remains of *Ardipithecus ramidus*, discussed in detail later, also helped to remove the presumption that humans walked with a bent-hip-bent-knee locomotor pattern (Lovejoy and McCollum 2010).

Lovejoy and McCollum (2010) hypothesize what the locomotor patterns of the last common ancestor between humans and chimps may have been like. They suggest that the LCA would have likely moved around the lower arboreal setting, as opposed to leaping across canopies at the top. This may have also put them closer to the ground, where they may have moved in small bursts as well. It is possible that this form of terrestrial transport may have occurred on four limbs instead of two, based on metacarpal evidence found in *Ardipithecus ramidus* (Lovejoy and McCollum 2010).

However, the evidence provided by *Ardipithecus ramidus* potentially provides an

important shift in these origins by making it unlikely that hominins were arboreal bipeds after a certain point in our evolution. The upright hanging anatomy seen in chimps and other apes were constructed for suspension, and modern humans have no similar anatomy that would suggest that we would have spent large amounts of time putting our arms up or putting weight on our shoulders (Lovejoy and McCollum 2010). Additionally, the anatomy of the lower limbs from remains from early hominins does not suggest they would have had the flexible ankle joint necessary for climbing or moving around in an arboreal setting (DeSilva 2009).

Because there has been substantial evidence that upright climbing in trees tends to lead to the development of a stiff lumbar spine, which would be unideal for bipedal motion, early hominins were likely not bipedal in an arboreal setting before being bipedal in a terrestrial setting. The authors mention that it would have been the differences in lumbar anatomy that fueled bipedal motion more so than pelvic anatomy, as was previously assumed (Lovejoy and McCollum 2010). Adjustments to the pelvis likely would have come after these adaptations to the spine.

Gathering and Carrying Food

Likely the most popular theory behind bipedal motion in humans is the Food-Carrying theory, which dictates essentially that hominins would have started to collect small amounts of food from trees and then would have needed to walk short distances to deposit it, or to collect more food from different trees. Studies and observational research have been done to examine how nonhuman primates cope with situations that may have been similar to those in the EEA. Research on Japanese Macaques helps provide support for bipedal locomotion as an adaptation for changes in food sources or collection (Hewes 1964).

It has already been suggested that as the environment in Africa moved from being forested to more open, early hominins would have needed to walk longer distances between food sources or may have even begun scavenging (Hewes 1964). Observations on macaques demonstrated that if one finds a food source that is too large to eat

quickly, the macaque will bipedally carry it back to a safer place. Other macaques who observed this process repeated it themselves (Hewes 1964). It appears as though the longest distance for this sprint of bipedal running or walking is usually around 30 m.

Studies on modern macaques have provided all sorts of evidence that help support this theory. A change in diet changed the behavior of the Macaques as they began to walk short distances bipedally, to access or collect more food. It is possible that they learned this in part from seeing the human observers walking on 2 ft (O'Higgins and Elton 2007).

An observational study on chimpanzees was done to test and observe the kinds of bipedal carrying behaviors they exhibited. The researchers changed the availability of certain kinds of nuts to see whether or not behaviors differed between moments of low-competition and high-competition for resources (Carvalho et al. 2012). During periods of high competition, instances of bipedal carrying quadrupled, and the number of resources carried at a time while walking bipedally was double that when the chimps were walking on three limbs. In additional studies, chimpanzees carried significantly larger amounts off food while walking bipedally in other scenarios. They were also able to transport all of their resources further, to private areas where they could be consumed without the risk of sharing. Environmental uncertainty and change may have created situations that favored those who could carry as many resources as possible (Carvalho et al. 2012).

These findings are in tangent with evidence presented by Hunt (1994). Chimpanzees prefer to gather food from smaller trees when possible and would usually be positioned on the ground while doing so. This meant that they did not have to do as much vertical climbing to get to the food they needed. If the chimpanzees of today are similar to our large-bodied primate ancestors, it is possible that these ancestors participated in similar terrestrial bipedal food gathering at smaller trees. He also noted that chimpanzees were able to collect more food while moving bipedally (Hunt 1994).

Feeding and gathering habits that combined terrestrial motion and arboreal climbing could be a potential explanation for this odd combination in Australopithecine anatomy. The evidence suggests that short bursts of bipedal walking combined with small amounts of arboreal climbing could have been the main protocol for getting food. The evidence suggests that australopithecines would have both gathered fruits by suspending themselves from branches, as potentially transported other foods across short distances on the ground (Hunt 1994).

Hypotheses concerning the carrying of tools have also been proposed; however, modern chimpanzees have been observed using and carrying tools quadrupedally, or holding a stick or rock with one limb and walking on the other three. This indicates that bipedalism is certainly not necessary to use tools, especially because there is no reason that tools need to be used while standing up. Other nonhuman primates show signs of using tools while sitting or kneeling (Hunt 1994). This implies that there would have to be other selective pressures causing bipedalism in tangent with tool use, for this to be a viable hypothesis. Infant carrying may have also influenced the evolution of bipedal motion, as the early australopithecines no longer had the flexible, grasping foot seen in other primates. Since they would have been unable to cling to their parents for long periods of time, parents would have needed to carry them (Watson et al. 2007).

Biology of Bipedalism

There is still a certain amount of disagreement between scholars on whether or not early hominins were tree-climbers, before adapting for terrestrial bipedalism. Fossil evidence indicates that bipedal locomotion likely emerged around four million years ago, again, during the Miocene period. There may have been an important split in lineage between what are now modern humans and chimpanzees, as it is hypothesized that our last common ancestor existed between four and eight million years ago, (DeSilva 2009). Many believe this ancestor would have been more closely related to modern chimpanzees than

modern humans. A comparison between the knee and ankle anatomy of modern chimpanzees and early hominins suggests that while these early humans may have been adept climbers, they were nowhere near as anatomically suited for it as modern chimpanzees are (DeSilva 2009). The joint angle of the tibia in chimpanzees is naturally bent, while that of humans is much more vertical, it would have likely been unsafe for early hominins to attempt to climb the way other primates did.

Bipedal motion in humans came with significant changes to skeletal structure. One specific change would be the fact that humans are upright, meaning the hands and arms can be used for carrying or gathering food (Lloyd du Brul 1962). Here (Lloyd du Brul 1962) insinuates that the origin of a bipedal posture came from this need to carry food, as was mentioned earlier. Additional skeletal changes include the reconstruction of the foot to be arched and elongated, the pelvis is flared, and knees are bent. Knees have also been reconstructed to maintain the weight of the human body while standing, without too much fatigue (Lloyd du Brul 1962). Additionally it is noted that flexibility in the hip and shoulder for humans is part of what defined human ability to walk on 2 ft without the added need of a tail for balance (Marks 1987).

The australopithecines appeared to have certain anatomical features that were almost transitional between earlier apes and modern humans, similar to what is seen in the later discovered *Ardipithecus ramidus* (Shipman 2010). Pelvic shape, for example, is much wider than that of modern chimpanzees, but is not nearly as bowl-shaped and circular as modern humans (Hunt 1994).

In summary of the pattern that we find in *Australopithecus afarensis*, the upper body features anatomy that appears to be ideal for arm-hanging, whereas the lower body appears to be more adept for bipedal walking. The curved finger bones and short lumbar indicate that this animal would have been a capable climber, likely hanging from tree branches to gather food (Hunt 1994; Tuttle 1981). However, the anatomy of the lower body of *Australopithecus afarensis* suggests that it would be sufficient for bipedal motion, although

this likely would have been less efficient and more stressful to the skeletal system, compared to bipedalism in modern humans. They likely wouldn't have been as habitually bipedal as modern humans are today (Hunt 1994).

Overall the comparison of morphology between modern humans, modern chimpanzees and *Australopithecus afarensis* suggests flaws in previous assumptions for the origins of bipedality. The presence of both arboreal upper anatomy and bipedal lower anatomy in *A. afarensis* indicates that their method for gathering food would have likely not been purely due to either terrestrial feeding or arboreal feeding (Hunt 1994).

Homo erectus demonstrates the first real indication of changes in post-cranial anatomy, compared to *Australopithecus afarensis*. Arboreal adaptations appear to stay all throughout the anatomy of the *Australopithecines* until the next species in the hominin lineage evolved. This is a sign that the arboreal upper body of the *australopithecines* must have been adaptive for one reason or another, of course, until it wasn't (Hunt 1994).

Ardipithecus Ramidus

In 2009, analysis was published on recent anthropological evidence that had been discovered in Ethiopia. The findings were that of 36 individuals from around 4.4 million years ago. The most complete skeleton was from a female, nicknamed "Ardi." Hers is currently the oldest hominin skeleton to date, and combined with the remains of the 35 others, provides compelling evidence that they likely walked bipedally. The full name for this group has been termed *Ardipithecus ramidus* (Shipman 2010).

It was originally believed that our large human brains evolved long before other human features such as bipedalism, or our dental anatomy, however these remains indicated that this was not the case. *Ardipithecus Ramidus* showed both indications of being bipedal, as well as having dentition that had human-like features. Much of her anatomy appears to be transitional between humans and chimps. She shares many features with both modern nonhuman apes, and modern hominins, however she appears to be evolving further away from our last common ancestor (Shipman 2010).

For many years, the remains of several different kinds of australopiths have been unearthed, all of whom are very different, but the one trait that they all shared, was that they were bipedal. While *Ardipithecus* was likely bipedal, they likely had the ability to maneuver around trees like most apes. Comparatively, their arboreal motion was likely similar to that of another early ape, the *Proconsul*, which was likely not as easy as earlier ancestors.

While *Ardipithecus* was likely not the last common ancestor between humans and chimpanzees, analyzing "Ardi's" remains can provide insight as to what that ancestor may have looked like or how it may have moved. Contrary to what may have been previously thought, *Ardipithecus ramidus* is not a transitional biped, she is a fully-established biped (Shipman 2010). As an additional hominin, she presents movement from potentially awkward bipedalism to more efficient bipedalism.

Conclusion

The evidence above provides several different and enticing arguments for the origins of bipedal locomotion. From changes in evolutionary environment suggesting the need for increased visibility, to adaptations that came from being bipedal in the previous arboreal setting. However, it appears that as more evidence on the Miocene hominins is discovered, the more complicated it becomes to explain their anatomy and potential behavior.

Modern non-human primates have demonstrated that there are ways of coping with certain environmental issues without needing to walk upright, indicating that the selective pressures that caused modern humans to evolve bipedal locomotion would have had to be intense and prolonged to justify a complete transformation in skeletal structure. To date it appears that the best evidence we have for studying hominin bipedalism comes from the recently discovered remains of *Ardipithecus ramidus*. Her anatomy still features arboreal adaptations in the upper body, but this could have been carryover from an earlier ancestor.

It is important to remember the amount of time it takes certain adaptations like this to evolve. When comparing the skeletons of modern humans with modern nonhuman apes it is clear that there was a complete structural reorganization. Even if this process started around 4.4 million years ago, it would have likely been hundreds of thousands of years before there were indications of truly bipedal skeletons, devoid of any arboreal upper body. Patience is required when sifting through the evidence, to deal with the fact that we, as modern humans, exist much further down the evolutionary line, and have much to thank our ancestors for.

Synonyms

Avian clutch size

Definition

The number of eggs laid in a single brood (or nest) by one or more female birds.

Introduction

Variation in the number of eggs laid in a single brood has fascinated researchers, especially ornithologists, since at least the 1940s. The number of eggs laid by a female varies enormously among taxonomic groups. Generally, it is constant and small, as in albatrosses and King Emperor penguins that lay one egg. In other species, clutch size is variable, and sometimes large, as in the partridge, which can lay between 14 and 20 eggs. The factors that are associated with the evolution of clutch size are, perhaps, one of the oldest topics in life history theory. To this end, several processes have been proposed that may influence selection on bird clutch size. Attempts to understand causes of avian clutch size variation range from intra- and interspecific studies, work on intrinsic (e.g., body mass, migratory behavior, nest type, diet) and extrinsic (e.g., latitude, temperature, precipitation, seasonality) potential drivers of such variation, to investigations of phylogenetic effects that may constrain clutch size variation. This entry provides a review of the information on bird clutch size, specifically from a perspective of the conflict of interest between parents and offspring over optimum clutch size.

David Lack and Clutch Size

The ornithologist David Lack was the first researcher to study the evolution of bird clutch size, in the 1940s (Lack 1947, 1948). Lack's work was seminal, as it attempted to explain variation in clutch size in terms of individual selection, while many researchers at the time considered that clutch size evolved to allow a population or species to persist. Lack reasoned that a bird would lay the number of eggs that maximized the number of young that successfully left the nest (i.e., fledged). In altricial birds – those whose newly hatched young are immobile and require extensive nourishment – Lack argued that the ability of the parents to feed their offspring was the main factor influencing the number of fledged young.

Lack's pioneering theory, however, assumed a harmonious setting within bird families. The theory assumed, at least for a single parent, that selection acts on clutch size to maximize the number of fledglings per clutch. However, what is optimal for a single parent need not be so for both parents, nor for the young involved.

Parent-Offspring Conflict

Conflicts of interest over the allocation of resources are a natural consequence of selection acting upon individuals that are not genetically identical. For instance, sexual reproduction leads to a situation in which parents and the offspring they produce are not genetically identical. Thus, natural selection could act in somewhat different ways on parents and their young. Robert Trivers, in the 1970s, explored the consequences and implications of this conflict in what is now known as the classical theory of parent-offspring conflict (Trivers 1974). Trivers' notable work was based upon Hamilton's rule (Hamilton 1964a, b) – another remarkable contribution that revolutionized our understanding of social evolution – to articulate a theory in which parental interests are challenged by offspring demanding more parental investment than is optimal from the parental point of view.

Briefly, Trivers' theory of parent-offspring conflict can be understood with the following simple situation (which can be extended to include other sources of conflict). The scenario involves a single parent that raises one offspring per breeding season. This parent will face a trade-off between continuing to invest in the current young and keeping the resources to improve its own survival or to invest in future offspring. The trade-off could manifest itself as several potential combinations of these mentioned life-history components. For instance, resources should be invested in the current offspring if the benefits in terms of its fitness are greater than the costs to future offspring, measured as their fitness.

Suppose that offspring, somehow, can influence parental resource allocation. The offspring

also faces a trade-off. This time, the trade-off is between resource being allocated to itself or to its future siblings. There is no doubt that the offspring benefits from receiving those resources. However, the costs, in terms of lost fitness to siblings, are substantial, because they all carry copies of the same genes. It is worth noting that the cost must be devalued by the relatedness between siblings. Therefore, the offspring will favor the diversion of resources towards itself when $benefit > relatedness * cost$, which is different from the criterion used by the parent ($benefit > cost$).

The “battleground” within which parent-offspring conflict takes place can take many forms. For instance, conflict can occur over the distribution of resources between current and future, unborn offspring, which is termed interbrood conflict. Another form of the conflict is that between members of the same brood, that is, intrabrood conflict. It is the latter that will be treated in more detail in the following section.

Clutch Size and Conflict

Most of what follows has been extensively discussed by Godfray and Parker (1991), thus readers should refer to that work for a more detailed discussion of the theory involving clutch size and conflict. For a more recent review of the topic, see Kilner and Hinde (2012). As the number of young in a clutch increases, the average fitness of the individual offspring is reduced. The main proposed mechanism underlying this decline in fitness is the competition between clutch members for limiting resources. Assuming this mechanism, clutch size is thus determined by the trade-off between the number and fitness of offspring in a clutch. What follows from this logic is that parents will be selected to produce a clutch size that maximizes the fitness returns of that clutch. The basic scenario, when all young have the same fitness, leads to the issue of augmenting the product of the number of young and average fitness. This result is known as the “Lack clutch size.”

From a parental perspective, it would be optimal if all offspring obtained their necessary share of resources, and not more, while not engaging in any type of intrabrood competition that could lead to a reduction in their fitness. Below, it is outlined how offspring competition within a brood generates conflict with the parent’s optimal “decision.” Then, an examination is presented on how competition between siblings, potentially, leads to selection on parents to reduce their clutch size. Chick hierarchies are discussed as a potential adaptation to reduce the negative effects of sibling competition. Finally, siblicide, possibly the most severe form of sibling conflict – when one sibling deliberately kills another – is discussed.

Intrabrood Sibling Conflict and Clutch Fitness

Bird sibling conflict and its evolution have most often been studied in the context of intrabrood competition between young and the evolution of begging. An assumption of how begging mediates the conflict between siblings is that increased begging translates into increased resources. In some bird species, it seems that parents allow the young to decide feeding priorities. Young frequently jostle among themselves to be closer to the parent when it arrives with food. However, in other species, parents seem to completely ignore begging, and feed, instead, the largest chick first and more frequently.

While increasing begging will, generally, lead to more individual benefits to the offspring producing the solicitation, begging can also incur costs. These costs can be experienced solely by the individual, when the costs are mainly metabolic, or they might be shared with brood mates, as with the attraction of predators that could be lured by the average levels of begging from the brood (Skutch 1949). Theoretical models predict that as clutch size increases, the reduction in parental fitness will also increase, both when costs are experienced individually or shared among brood mates. The extent of the reduction in fitness is dependent on clutch size and also on how the costs are spread among the brood. But, the main message is that competition among offspring will lead to a reduction in the fitness of the clutch.

Sibling Competition and Selection on Clutch Size

Sibling competition, as discussed above, potentially leads to a reduction in offspring fitness. Therefore, sibling conflict may act as a selective pressure that will lead to a reduction in clutch size. The underlying mechanism is that in reduced clutches, there is more resource available *per capita*. Theoretical models predict that forms of sibling conflict (namely the shared or individual costs) will usually reduce clutch size in the order of 20–30 %, which is substantial, when compared to a scenario of no sibling competition.

Offspring Hierarchies

Offspring do not all have the same competitive abilities. Several bird species begin to incubate their eggs before clutch completion, leading to an asynchrony in hatching, which leads to a hierarchy in chick size. The resulting differences in chick size are likely to be associated with different competitive abilities. Sibling hierarchies can thus influence resource distribution and competitive solicitation. The study of sibling hierarchies has been of much interest to evolutionary biologists, with as much as eight different hypotheses proposed as explanations for the evolution of the asymmetry between young. One proposition is that the hierarchy is an adaptation by the parent to reduce sibling competition. The underlying reasoning is that the hierarchy leads to a preemptive division of resources, which minimizes fitness costs raised by competition.

Siblicide

Offspring killing one another in a brood is a well-known process that influences brood size in birds (Mock 2004). Siblicide is common among raptors and also in cranes, gannets and boobies, herons, pelicans, penguins, and skuas. When siblicide occurs in a species, it may be either facultative or obligate. The former may occur when, for instance, environmental conditions are unfavorable, and parents cannot provide enough resources to fledge successfully more than one young. In species with obligate siblicide, on the

other hand, parents may lay a second or third egg as an insurance against the failure of the first egg.

Conclusion

This chapter has discussed that clutch size is often a product of several intrinsic and extrinsic factors that shape selective pressures on the number of eggs laid by female birds. Individual parents and offspring have different fitness optima, due to their nonidentical genetic constitution. This difference may lead to a conflict between each individual's interests, and the consequences of the conflict can be detrimental to both parts involved. While offspring have little – or no – influence on the determination of the number of eggs that will be laid, competition between members of the same brood has important evolutionary implications for clutch size.

Bird Tool Use

Nathan Emery

Queen Mary University of London, London, UK

Causal reasoning; Object manipulation; Physical cognition

Definition

Birds using an unattached object as a means of (better) attaining a goal when their beak or talon is not sufficient.

Introduction

The ability to use and make tools has played a significant role in our notion of human cognitive evolution ever since Darwin proposed that our minds evolved like our bodies. Tool use was seen as one of our defining features, until Jane Goodall discovered that chimpanzees also made and used a variety of different tools. Although Goodall's observations eventually opened the door to the comparative study of tool use in other primates, otters, rodents, cetaceans, birds, reptiles, fish, amphibians, and even some invertebrates, the idea that nonhuman animals can use and even make tools has been a bitter pill for some to swallow. Tool use has become so entrenched in our idea of what it means to be human, that its very notion is intimately tied to that of human intelligence; tool use has to be a special and highly cognitive behavior. Studies in birds have been at the forefront of unraveling the tangled relationship between tool use and intelligence and revealing some intriguing findings along the way.

Some Clarifications

Once Goodall's studies had been made public, the idea that chimpanzees habitually used and made

tools was rapidly accepted, especially with the publication of photographs in *National Geographic* and ultimately film of the apes in action. Chimpanzees possess hands like ours, they have a similar visual system (and subsequent hand-eye coordination), and they have large brains. Such acceptance was not going to be so easy for birds, which do not have the same obvious manipulative limbs, comparatively small brains and supposedly reduced mental capacities. However, Gavin Hunt published an important paper reporting that New Caledonian crows (NCC) made and used two types of tools: specially shaped leaf tools differing in the number of design steps required to produce them and hooked stick tools (Hunt 1996). Other cases of avian tool use have become apparent: woodpecker finches on the Galapagos Islands removed spines from cactus to use as tools to probe into cavities and into bark to retrieve grubs, green heron used "bait" to lure fish to the surface to be more easily taken as food (Higuichi 1988), and Egyptian vultures dropped rocks onto ostrich eggs in order to gain access to the contents inside (Thouless et al. 1989). The most recent definitive survey of animal tool use by Shumaker et al. (2011) reported 35 different categories of avian tool use, including dropping, throwing, baiting, hammering, digging, reaching, inserting, and absorbing, using a variety of natural and manmade objects, across a diverse range of bird groups, but with the highest frequency found in the corvids (crows, jays, magpies, and ravens).

Despite this diversity of tool use in birds, many cases are ambiguous and not from strictly scientific sources. One issue is whether a case of object manipulation should be interpreted as tool use at all. To some degree, this depends on whether the behavior can be attributed as intentional or goal-directed. For example, black eagles and ravens have both been described dropping sticks and stones onto humans from above. This act has been interpreted both from a low-level perspective, as part of a mobbing response towards an intruder, and from a high-level perspective, as an expression of frustration. However, for both interpretations, the mechanics of the act are the same. When comparing dropping a nut onto a rock versus dropping a rock onto a nut, both actions may

be performed by the same individual as part of its behavioral repertoire; however, only the latter can be interpreted as tool use (by known criteria). Please note that deriving this interpretation does not assume that one action is more cognitively complex than the other (see later). Dropping a nut when flying may require certain skills in assessing the correct height from which to drop certain sizes of nuts, the cost: benefit ratio of height to number of conspecifics present (so that the contents of nut may be reached before competitors), the speed required to produce an adequate drop to initiate a substantial break in the shell, the appropriate surface on which to launch the nut onto, etc. (Zach 1979). By comparison, dropping a rock onto a nut may only require the application of a simpler rule – “choose the largest rock you can carry, and drop it onto the nut until it breaks”.

Another potential problem with many of the records of avian tool use is the fact that many are anecdotes, reporting only rare or single occurrences, rather than cases that have been the focus of systematic study and experimentation. This does not mean these records have no value, rather they reinforce the view that tool use in birds is rare and except in a few cases, nonhabitual. Of these cases, found only in captivity and which have been studied using empirical methods, not all subjects perform the behaviors, and the actions are only used in a specific context – the procurement of food out of beak reach.

What Is Tool Use?

Despite sophisticated tool use in a limited number of avian species in captivity (and even fewer examples in the wild), the frequency of tool use is much greater in the apes, both in terms of the diversity of tool types (and functions) and their flexibility. However, the cognition underlying tool use in birds does not appear to be less sophisticated than in apes (and there is good evidence that the physical cognition of crows in some tool-related problems is more sophisticated than demonstrated by apes). Shumaker and colleagues' (2011) survey of animal tool use documents

dozens of examples of tool use in birds, but there are some issues of ambiguity about what may be classified as **true** or **borderline tool use**. A classic illustrative example is the difference between a song thrush repeatedly bashing a snail onto a path or a large stone in order to break the shell and eat the contents. Some might argue that the thrush is using the hard rock surface as a tool (as it cannot open the shell without this external object). However, this is presented typically as borderline tool use as the bird has not detached the rock to be used as a tool that can be carried and manipulated independent of its location. By comparison, Egyptian vultures pick up rocks and drop them onto ostrich eggs in order to break open the shells and eat the contents. In this very similar case, this has been classified as true tool use, as the tool is a detached object (rock) used to procure something (food) ordinarily incapable of being accessed without a tool. Similarly, crows dropping hard-shelled nuts onto roads in Japan or California in order to crack them open on a hard surface (and increase this possibility by dropping them onto roads for cars to drive over) is not an example of tool use, albeit an impressive display of problem-solving (Cristol et al. 1997). This is also a case of borderline tool use, as even using a car to crack open the nuts is not tool use as defined.

The difference between what is viewed as tool use and what is not can be subtle, but it is important when trying to determine whether there are taxa unique tool capabilities and whether these capabilities are dependent on cognition. Perhaps most interestingly, there appear to be brain size differences between avian species that are true tool users and species that only use borderline tools (Lebeuvre et al. 2002), with the true tool users having larger (relative) brains and a larger nidopallium. Although the nidopallium has been implicated in complex cognition in birds, whether having a larger nidopallium reflects a cognitive advantage is currently not known.

Anatomy of a Tool User

Can any bird become a tool user? Are there conditions (morphological, physiological, motivational,

ecological) that make tool use more or less likely? The fact that tool use (especially habitual tool use) is rare suggests that a number of preconditions need to be in place in order for tool use to have evolved in one species but not another. This is especially clear when assessing tool use capacities in closely related species. For example, despite there being 45 *Corvus* species, only one, NCCs, habitually make and use tools. A number of other *Corvus*, such as rooks, readily use tools in captivity (Bird and Emery 2009a), but there has never been any reported case of tool use in this species in the wild. Fundamentally, why should a species evolve using a tool over evolving a physical specialization adapted for procuring the same food as acquired through tool use, such as a specialized beak? The beaks of finches on the Galapagos Islands are a classic case of morphological adaptations for foraging. Seed-eating finches have beaks adapted for eating seeds, whereas fruit-eating finches have beaks adapted for eating fruit, etc. Woodpecker finches did not evolve beaks suited to any particular diet but which are suited for manipulating tools. One problem with morphological adaptations is their rigidity. They have evolved for one purpose, which makes them difficult to apply to different problems: a seed-eating beak cannot easily be used for eating fruit and vice versa. It is not clear why woodpecker finches (or indeed NCC) did not evolve specialized beaks, but this fact may have sped up the journey to tool use in these two species. Both species have short, straight beaks that help them hold tools with greater grip strength but also with an increased control of subtle movements. A failure to specialize may have driven these species to generalize their diets (omnivory), which in turn increased opportunities for foraging on a wide variety of plant and animal species, some of which were only accessible with a tool.

These species also possess other morphological adaptations. NCCs, for example, have the widest binocular visual overlap of any bird so far tested (Troschianko et al. 2012). As such, the contralateral eye can see the working end of a stick tool held in the beak on the opposite side. However, Martinho et al. (2014) suggest that because crows prefer to hold the tool in such a way that

the tip is on the same side as their preferred eye, they control the tool using monocular vision. It is not clear what advantage either system would provide.

Tool Use in the Wild: Four Case Studies

Despite a plethora of tool use reports in wild birds, there is not the space to describe them all here. Yet, a brief discussion of some cases of natural and habitual tool use is worthwhile in order to demonstrate the diversity of different uses of objects as tools, and the range of species that use external objects for actions which their bodies alone are incapable. The cases reported here were chosen because they have been the best studied and provide unambiguous evidence for true tool use.

Egyptian Vultures (*Neophron percnopterus*)

Egyptian vultures have been observed carrying stones in their talons, carrying them aloft and then either throwing them onto ostrich eggs or picking up rocks in their beaks and carefully dropping them onto eggs. This is an example of drop tool use (Shumaker et al. 2011). An experimental study of this behavior found no evidence that this behavior was learned socially, and vultures tended to prefer rounded or egg-shaped stones rather than jagged rocks as missiles (Thouless et al. 1989). It is not clear whether these preferences relate to the stones' efficiency or the subject's previous experience. Studies have yet to be performed concerning the vultures' understanding of properties of the rock (size, shape, weight, height from which the rock needed to be dropped, etc.) or the egg (shell strength, breakage point, etc.).

Green-Backed Herons (*Ardeola striata*)

Herons across different continents have been observed using lures, such as insects, bread, twigs, and feathers held in the tip of the bill, as bait for fish, which take the bait, and then subsequently are caught by the heron holding the bait (Ruxton and Hansell 2011). This is an example of bait tool use (Shumaker et al. 2011). Seven out of

12 species of herons catch fish this way, displaying either active or passive bait-fishing. Active bait-fishing uses a lure either dropped and left or held in the bill; as such it is a supposed demonstration of goal-directed behavior. Passive bait-fishing are cases when a heron benefits from a fisherman dropping a lure or one naturally floating in the water, and then taking the fish attracted to that lure. It is not clear how active bait-fishing developed, perhaps after forming a causal link between observing a fish take a bait and intentionally using a bait to catch a fish. Although individual differences in this behavior have been studied, subsequently finding that not all individuals perform this behavior or they differ in the level of their skill (and subsequently success), little is known about the underlying cognitive abilities involved (Higuchi 1988).

Woodpecker Finches (*Cactospiza pallida*)

Woodpecker finches are found exclusively on the Galapagos Islands, primarily Santa Cruz. They use twigs or cactus spines (either found or naturally detached) which they hold in their beaks to poke into bark to dislodge their prey, wood-boring beetle larvae. This is an example of probing tool use (Shumaker et al. 2011). In many cases, the finches modify these tools, shortening them so they are easier to handle. This form of tool use seems to be innate, as juvenile finches do not need to observe an adult before they use their first tool (Tebbich et al. 2001). However, whether finches use a tool depends on where they are located on Santa Cruz and the season. Tool use only occurs in the arid zone and only in the dry season. In the wet season, the grubs move to the surface and so can easily be accessed without tools, whereas in the dry season, the grubs bury themselves deep under tree bark (Tebbich et al. 2002). Finches acquire approximately 50 % of their total food from prey captured using tools in the dry season in the arid zone.

New Caledonian Crows (*Corvus moneduloides*)

Like woodpecker finches, NCCs appear to fill in the ecological niche usually occupied by woodpeckers on the mainland. Huge grubs are found under tree bark or buried within leaf litter that are

unreachable without a tool to prize them out. NCCs use three types of tools: probing tools of different shapes made from the tough, barbed leaflets of *Pandanus* plants and sticks either with or without hooked ends (Hunt 1996). Both tools are created using a multistep process (see “Tool Manufacture”). Both types of tool utilize a hook, either natural barbs located on one side of the leaf or a hook that is created and then fashioned by removing the stick from the original tree. These hooks function in levering a grub from out of its otherwise inaccessible hiding place. There are four main types of leaf tools: wide, narrow, single step, and multi-step, with the narrow and multi-step the more complex to make. These different types are not found distributed equally across New Caledonia, suggesting that the different tool types are either environmentally constrained in some way (e.g., by the amount or quality of the raw material), which is unlikely as they are made from the same plant, or individuals have adapted an original design into innovative new designs that have been copied and taken elsewhere, which has been proposed as a case of cumulative cultural evolution (a trait that has been suggested to be uniquely human). This process could have been the result of crows learning a new design from watching other crows or possibly extrapolating from the leaf counterparts left after a tool is made, then moving to a different population (perhaps after leaving the family) and the new design spreading through the new population.

Tool Use in Captivity: Three Case Studies

Despite the limited number of birds that regularly use tools in the wild, there are other birds that are capable of using objects as tools in captivity. Why? Most birds are beautifully adapted to gaining and processing food with bodily adornments evolved through millions of years, namely beaks (and feet; parrots). Although tool use may provide a cognitive constraint on whether tool use evolves in one species, but not another, we think this is unlikely in closely related species, especially those for which we find evidence for

similar cognitive abilities in tasks not dependent on using tools (Teschke et al. 2011). It is more likely that ecological and/or morphological constraints have driven one species to use a tool and not another. Indeed, there is accumulating evidence that tool users do not outperform closely related species on tool-related or other cognitive tasks (see below).

Goffin's Cockatoos (*Cacatua goffini*)

Goffin's cockatoos are typically found in Indonesia but are a popular pet. They have not been reported to use tools in the wild, although little field work has been performed on this species, due to difficulties in tracking them in the dense forests where they live (a pattern seen for many Psittaciformes). However, a single individual, Figaro, housed in a large captive group in Vienna, Austria, was discovered to have taken long elongated splinters from his wooden aviary to rake in an out of reach cashew nut (Auersperg et al. 2012). Figaro made the tool shorter, presumably so that it was easier to handle. Parrots are relatively rare tool users, probably because the types of foods they naturally encounter and subsequently incorporate into their diet – despite being tough skinned or possessing shells – can be processed using a combination of very tough beaks that shear and smash and gripping feet that hold such items steady when being manipulated with the beak. In this current example, such anatomical adaptations would have been useless for the simpler act of retrieving an out of reach object.

Kea (*Nestor notabilis*)

Kea are alpine parrots living in the mountains of the Southern Island of New Zealand. Like many island birds, they have quickly taken over niches typically occupied by other animals, in the case of kea, carrion birds (although like other carrion feeders, they are omnivorous). Compared to the beak of a cockatoo, which is ideal for crushing and peeling off the tough shells of nuts and the skin of hard fruit, keas beaks are curved and adapted to tearing flesh. This they do, even on live sheep, to the consternation of farmers. As with cockatoos, there may be little reason for kea to use tools in the

wild, but in captivity they can use sticks as tools (Auersperg et al. 2011). Numerous cognitive tests have revealed that kea solve novel problems, especially when learning from others (Huber and Gajdon 2006).

Rooks (*Corvus frugilegus*)

Rooks are corvids that have a wide distribution across Europe and Asia as well as an introduced population in New Zealand. Their behavior has been studied quite extensively, especially their breeding biology and social interactions, yet there are no reports of them using tools. This might be because they have rather long beaks compared to other crows, which are used for digging deep into soil for earthworms as well as creating elaborate cache sites. Such an anatomical adaptation leaves little requirement for a tool. It is a different story for captive rooks who have demonstrated the flexible use and understanding of tools, such as stones and sticks in multiple problem-solving contexts (Seed et al. 2006; Bird and Emery 2009a, 2009b). For example, when presented with a puzzle-box in which a collapsible platform held up by a magnet can be triggered to release the treat it is holding up, it took only five trials for a number of rooks to learn the affordances of this task (where stones could be accidentally knocked into the puzzle-box, and therefore demonstrate how it works). The birds rapidly applied this knowledge to using the best tool for a specific function, such as dropping a large stone into a wide tube or a small or thin stone into a narrow tube. In a different task, in which a small bucket containing food was located at the bottom of a tube, rooks were provided with wooden V-shaped hooks, either functional (the V was turned upright) or nonfunctional (the V pointed downwards). Rooks spontaneously chose the functional hook to retrieve the bucket and get the reward (Bird and Emery 2009a).

Is Nest-Building an Example of Tool Use?

Another consideration that is almost unique to birds is the question of whether nest-building is

a specialized form of tool use. Until recently, this would not have been seen as an important question, as the act of nest-building was seen as a purely instinctual behavior, under genetic and hormonal control, and little within the realms of comparative cognitive science (Hansell 2000). However, recently the psychological processes underlying nest-building have become the focus of intense scrutiny (Breen et al. 2016), revealing hitherto unheard of roles for learning and physical cognition that lend themselves to a more complex interpretation of this ubiquitous behavior. If we apply the definition of tool use to nest-building, mechanistically they are very similar. Indeed, in some respects, nest-building is a more complex mechanical process than all known forms of avian tool use (Breen et al. 2016). However, the fact that a behavior appears complex does not mean that it is complex. So it is with tool use, so it (probably) is with nest-building. However, the very same actions that are essential for selecting an appropriate tool and using it correctly within a specific context are basically the same processes for both tool use and nest-building. This area is in need of further research.

Tool Use and the Avian Brain

Tool use is dependent on a wide suite of abilities, such as motor skill learning, beak(hand)–eye coordination, and causal reasoning. This is amplified when considering a taxon which does not have hands, and has to both hold and manipulate an object using the beak (and very occasionally the feet), that is located close to their eyes. As such, tool use should also be dependent on a highly evolved brain. Although there are no studies of the neural basis of tool use in birds, a number of correlates between the propensity to use and make tools and some measure of the brain (absolute and relative size of the whole brain, pallium or subdivisions of the pallium, size of the cerebellum or its subdivisions, or even specialized neurons) have been reported. For example, there is a clear relationship between brain (and nidopallium) size and the frequency of reported cases of true tool use (Lefebvre

et al. 2002), which is more prevalent in corvids and parrots (which tend to have larger brains anyway). Within corvids, NCCs have larger association areas, such as the nidopallium and mesopallium than other corvids (Melhorn et al. 2010), but it is not clear what this size increase actually means with regard to cognition.

Even if we accept that cognition plays some role in tool use (however, see below), we are less likely to argue that it is not a complex manual skill. As such, we might expect that the area of the brain most closely associated with manual dexterity and motor learning, the cerebellum, should be different in tool users compared to nontool users. Indeed, tool-using birds have a more significantly folded cerebellum (i.e., increased foliation) than nontool using birds (Iwaniuk et al. 2009). Again, how this relates to the production of a complex skill is unknown.

Is Tool Use Intelligent?

Despite the ubiquity of tool use across the animal kingdom, to the public, the ability to use a tool is synonymous with intelligence: humans can use tools, so any creature that can also use a tool must be intelligent. Is there any experimental evidence to support this claim? Comparative psychologists have designed a number of clever tasks in an attempt to reveal what an animal may understand about the property of an object that allows it to be a functional tool in one context but not in another. Tasks have also been designed to establish whether animals understand the concept of causality; that their actions in using a tool have specific consequences (effects). Perhaps surprisingly, animals that are highly proficient tool users in the wild are no better at using tools appropriately in a problem-solving context in captivity. For example, a classic test of causal reasoning is the trap tube task. A subject is presented with a transparent tube, with food located at its center. On the underside of the tube is a trap into which the food will fall if moved into it. To remove the food from the tube, the subject has to insert a tool and use it to maneuver the food out of the tube while avoiding the trap. Chimpanzees,

capuchins, and woodpecker finches eventually learn after dozens of trials to produce the correct behavior (insert a stick into the correct side) and remove the treat (Emery and Clayton 2009). However, when the tube is inverted, so the trap no longer presents an obstacle to removing the treat, subjects persevere on poking the tool into the side in which they had previously been successful. Some commentators have stated that this suggests these subjects do not understand the task, despite the fact that the rational choice is to continue what has been previously been successful. An adaptation of this task, with the addition of a nonfunctional trap in which food can either fall through or pass over a solid base (two-trap-tube task), was also adapted for use by non-tool-using species, such as rooks, by presenting a tool already inserted into the tube, so all the subject had to do was pull from the correct side to avoid the functional trap. Rooks were capable of solving both adaptations more rapidly than chimpanzees could solve the original task, transferring to the alternate version, and one bird also solved a version in which possible learning cues were removed, suggesting causal reasoning (Seed et al. 2006). NCCs tested on a similar version performed like rooks and also transferred to a novel trap table task (Taylor et al. 2009), whereas there was little evidence that woodpecker finches could solve this task, with the exception of one bird (Teschke and Tebbich 2011).

In order to determine whether tool users possess an advantage over nontool users in terms of cognition, one needs to design a task that tests for physical reasoning but which is not dependent on the animal performing the task being a tool user. The two-trap tube task asks the subject nothing more than the ability to pull a stick; the cognitive requirements are dependent on the ability to discriminate between different courses of action and their consequences. A different task designed for tool users and nontool users alike is the collapsible platform task (Bird and Emery 2009a). A perspex box with a vertical tube on top contains a platform inside held upright with a magnet. Dropping an object of sufficient weight/size/shape into the tube dislodges the platform and releases a reward to the

subject. By adjusting the width of the tube and the strength of the magnet, a subject can be tested for their understanding of what constitutes a functional tool. For example, a large stone can be placed into a wide tube but not a narrow tube or a small stone may be too light to displace a stronger magnet or a long stone may fit inside a narrow tube, but only if oriented lengthways. Bird and Emery (2009a) tested rooks on a series of these problems after initially training them to place stones into the tube on top of the test box (using shaping and rapid learned). The rooks performed successfully on the first or second trial of every problem they were presented, including transferring to sticks of different sizes and shapes, as well as presenting cases where on a previous trial they had been successful (i.e., the tool was functional), whereas on the next trial the context changed, and the same tool was no longer functional. The rooks were also successful on sequential tool use tasks, in which they had to choose one tool in order to gain access to a second tool that could be used to access food.

A different task in which subjects were required to drop stones into a tube was designed around an Aesop's Fable called "The Crow and the Pitcher" in which a thirsty crow spies a pitcher of water, but the level of the water is too low for the crow to drink. The crow hits upon the idea to add stones to the pitcher, so raising the water to a high enough level to drink. Bird and Emery (2009b) designed a comparable task with a tasty treat floating on the surface of the water. Rooks (with experience of the collapsible platform task) started adding stones into the water-filled tube until they could reach the worm on the surface. They tended to choose the largest stones and rapidly learned to avoid placing stones into a sand-filled tube when presented alongside a water-filled tube. Additional studies using the Aesop's Fable task have been performed on other non-tool-using birds such as Eurasian jays (Cheke et al. 2011) as well as tool-using New Caledonian crows (Taylor et al. 2011; Logan et al. Taylor 2014) with a number of very clever variants designed to determine whether the birds' performance was due to instrumental conditioning, causal reasoning, or even insight.

Importantly, there does not appear to be any difference between the performance of tool-using crows and other non-tool-using corvids.

Conclusion

Birds as a group are as proficient tool users as primates, but their interest in tools tends to be restricted to the acquisition of food. By comparison, primate tool use is more diversified across different technical and social functions. It is not yet clear what role tool use may have played in the evolution of avian cognition, as so few species regularly use tools in the wild, and the performance of tool-using and non-tool-using species on tests of physical cognition does not appear to differ. It is suggested that tool use in birds may have evolved as the consequence of morphological adaptations and environmental factors, rather than some increase in brain power leading to cognitive specializations.

Definition

Any method that prevents the conception of offspring in sexually active women.

Introduction

Birth control became popular in the 1960s when it was introduced to the public as a means of preventing unwanted pregnancy, which has played a major role in the movement of sexual liberation for women (Cobey et al. 2011). Birth control is unique to humans because it grants women the decision to choose who they want to conceive offspring with while giving them the liberty to engage in copulation with those they do not want to bare children with. Of course, sexual intercourse without the implication of pregnancy only works if the method of birth control is used correctly. Hormonal contraceptives work by mimicking pregnancy in the female body through the implementation of synthetic hormones like estrogen and progesterin, disrupting the natural hormonal cycle. It does this by preventing ovarian hormone production. Also, since such a method is evolutionarily unnatural, there are several physiological, psychological, and behavioral implications for taking birth control. Additionally, recent studies on birth control have revealed partially concealed ovulation across humans, since it has been shown that naturally ovulating women emit more signals to the opposite sex during peak

ovulation with men detecting such signals for successful mating as compared to unnaturally cycling women.

The Evolutionary Roots of Birth Control

In present day, there are several different types of hormonal contraceptives on the market ranging from oral contraceptives (i.e., birth control pills) to the use of a patch that absorbs hormones through the skin and into the bloodstream. Oral contraceptives are the most popular form of birth control, making up 82% of all birth control users (Wellington et al. 2012). Other methods of hormonal birth control with varying effectiveness include vaginal rings, injectables, and implants. Methods of birth control that do not emit hormones in order to interfere with the natural ovulatory cycle include IUDs (i.e., intrauterine devices that are inserted in the uterus and into the fallopian tubes, blocking the sperm from fertilizing eggs located in the ovaries of women), condoms (both female and male), and sterilization. Lastly, women can track their ovulatory cycles to predict whether or not they are experiencing peak ovulation and only choose to have sexual intercourse on the days they are least likely to get pregnant. Of course, this type of birth control is the least effective when it comes to both contracting sexually transmitted infections (STIs) and preventing pregnancy. That is, the human body is designed to get pregnant, and each body has its own unique biology, so it's better to be safe and use other methods of birth control alongside the natural method.

As aforementioned, women are more likely to conceive a child during peak ovulation. According to the typical female ovulatory cycle, there are 5 to 6 days during a complete cycle when women can conceive (Carmen et al. 2013). The ovulatory cycle lasts about 28 days with the conception period occurring at the beginning of each cycle. There are three total phases in the ovulatory cycle: menses, follicular, and luteal. During the luteal phase, the risk of pregnancy is at its lowest, and progesterone levels are at its highest point. Ovulation occurs

during the menses cycle and for only 1 day out of the 28-day cycle. On this day, the vagina produces a substance chemistry that allows sperm to survive in the female reproductive system. That is, during this time period, the sperm is capable of fertilizing an ova over the course of about 5 days, as long as it is encapsulated in the right fluid chemistry at room temperature. On the days where the window of peak ovulation is not open, the female vagina actually produces a fluid chemistry that has a spermicidal effect, making it much harder to conceive a child on those days. Such a complex cycle explains why humans did not conceive an insurmountable amount of offspring during ancestral times and why the use of natural birth control (i.e., having intercourse in accordance to one's ovulatory cycle in order to increase or decrease the likelihood of pregnancy) is more effective (75–98%) than many might think. On top of that, women were usually pregnant or breastfeeding during ancestral times, which prevented them from ovulating frequently.

During peak ovulation, it has been observed that women behave differently as compared to times when they are not ovulating, assumedly to attract more desirable mates for reproductive success (Carmen et al. 2013). According to Gangestad and Thornhill's (1998) ovulatory-shift hypothesis, women are more likely to engage in behaviors to attract mates during periods of high fertility. Such behaviors include sexual opportunism (i.e., making sexual advances when available) and more positive attitudes, sexual interest, infidelity, and willingness to engage in sexual activity with unfamiliar men (Geher 2014).

These behavioral changes during the ovulatory cycle are related to mating intelligence (MI). Mating intelligence is considered to be the reproductive system of the mind. In other words, MI is the degree of cognitive ability to successfully engage in proper mating strategies that will increase the chance of choosing the most fit partner to assure the reproduction of vital offspring. Cognitive abilities that comprise of MI include mate choice, acquiring the targeted mate, mate retention, and mate decisions regarding the dissolution of

courtship. Additionally, predictors of high MI consist of greater and more frequent acts of both giving and receiving oral sex (i.e., indicators of courtship and determining mating value) and reproductive success (RS). Sensibly, it has been observed that MI significantly increases during peak fertility as preferences to access “good genes” increase. Because birth control interferes with the natural ovulatory cycle, the absence of peak ovulation in women on hormonal contraceptives makes it less likely for them to experience a spike in MI during times when they would usually be ovulating (Carmen et al. 2013).

As mentioned, hormonal birth control works by mimicking pregnancy in the female body through the implementation of synthetic hormones like estrogen and progesterin, disrupting the natural hormonal cycle. Because the female body believes it is pregnant, it cannot go through its natural process of fluctuating hormones suitable for reproductive success. In other words, the female body already thinks it succeeded in conceiving a child, so it does not need to go through the process of ovulation for the duration of the pseudopregnancy or the length of time the female is using birth control.

During a natural ovulatory cycle, estradiol levels are highest at peak ovulation. These high levels of estradiol are believed to be the cause of behavioral changes observed across women, elevating mating intelligence. Additionally, men are more receptive to such behavioral signals indicating a rise of MI. For example, a study performed on female strippers reported that men are far more likely to tip female strippers when they are ovulating as compared to female strippers who are not ovulating or who are on birth control. Such estradiol-linked MI behaviors that could account for this phenomenon include elevated female initiations for sex, a greater masculine preference, more risk-taking behaviors, an elevated tendency to wear skimpy clothing, higher instances of erotic movement and dancing, and more symmetrical body parts (Geher 2014). In addition to bigger tips, males reported feeling more attracted to the voices and scents of ovulating women. Men also found photos of ovulating women to be more attractive. In

accordance, these findings are linked to a concept known as concealed ovulation.

Concealed ovulation is when female organisms and their suitors are unaware of when females are ovulating. Due to findings that support a change in female behaviors and male receptiveness during female peak ovulation, it turns out humans experience a more low-key form of overt ovulation. That is, if female humans really had concealed ovulation, their mating patterns would stay the same regardless of whether or not they were ovulating or on birth control. Because of this, it is more suitable to say that human females experience partially concealed ovulation, since most of their elevated mating behaviors during peak ovulation are somewhat below awareness or the threshold of consciousness.

Since hormonal birth control is not a natural mechanism in the human species, it understandably does not go without its physiological, psychological, and behavioral implications or side effects. In a sense, birth control goes directly against the environment of evolutionary adaptiveness (EEA). According to the evolutionary theory, all organisms are meant to survive and pass on their genes through reproductive success. Birth control halts that natural process. That is, with the freedom for women to control their own fertility, there are inevitable consequences.

On a physiological level, birth control has been shown to elevate the risk of myocardial infarction (heart attack), ischemic stroke, and blood clots. On the other hand, birth control has also been shown to decrease the prevalence of ovarian and endometrial cancer (Welling et al. 2012). Psychologically, birth control has been reported to elevate intense affective responses toward infidelity and sexual jealousy, which is thought to be a consequence of synthetic estradiol in birth control, but not due to synthetic progesterin (i.e., another substance that is usually in birth control). Other psychological effects include higher rates of depression and a decreased interest in sex.

Juxtaposed with the increased MI behaviors experienced by naturally cycling women during peak ovulation, women on birth control experience a whole host of different “synthetic-hormone-induced” reactionary behaviors. Such

reported behaviors include greater mate retention tactics (e.g., emotional manipulation, physical violence, intrasexual competition) from increased levels of emotional jealousy, greater engagement in short-term mating as compared to long-term mating throughout the entire ovulatory cycle, more sexual partners, and reduced sexual functioning (Welling et al. 2012). Overall, the absence of natural hormones throws typical mating strategies out of whack and decreases cyclical and perhaps more beneficial mating intelligence tactics across women. The trade-off, of course, is preventing pregnancy, which is a result of our Western cultural landscape at a time where personal success has the tendency to trump building a family at a young age.

Aside from the negative implications of birth control, there are objective differences between women who use birth control as compared to women who do not. One difference is affect variability. Naturally cycling women experience greater affect variability during their cycle than women on birth control. That is, many women experience greater mood stability while taking birth control because there are no longer mood swings associated with the varying influx of hormones during the natural ovulatory cycle. In addition, this stabilizing effect is especially true for women who experience intense premenstrual emotional symptoms associated with low progesterone to estrogen ratios (Oinonen and Mazmanian 2002). The greatest difference in affect variability occurs during menstruation (i.e., withdrawal bleeding) when naturally cycling women have a tendency to experience elevated negative mood states as compared to unnaturally cycling women.

Interestingly, Natale and Albertazzi's (2006) study on mood swings across the menstrual cycle found that there were only significant mood differences between naturally cycling women and those who were on birth control when the women who were on birth control had premenstrual syndrome. Despite this, the ovulatory cycle (natural or unnatural) generally does impact mood and mood patterns across all women, especially when it comes to depression-dejection symptoms. For all women, it is typical for mood to

worsen before menstruation and for mood to lighten post-menstruation. Overall, birth control pills help to better stabilize mood in women suffering from premenstrual syndrome, but do not significantly (albeit slightly) stabilize or improve mood across healthy individuals. These findings suggest that more research needs to be done in order to determine how much birth control really does affect cyclical mood states during the ovulatory cycle but suggests differences do exist, especially for those who suffer premenstrual symptoms out of the range of normalcy. The takeaway here is that the differences are more subtle than one might think.

Another studied change in behavior between naturally and unnaturally cycling women is sexual interest and response (Graham et al. 2007). Birth control decreases the level of testosterone in a woman's body, which is responsible for a healthy libido. Because of this, it has been reported that women who have been on birth control for at least 3 months show a decrease in sexual interest and response. Also, according to Graham et al. (2007), there is a relationship between decreased libido and a lower frequency of sexual thoughts across birth control participants. However, despite these findings, many birth control participants did not experience a lowered sex drive or lowered sexual satisfaction with their partner. Such findings suggest, again, that more research needs to be done on how much the testosterone-lowering effects of birth control actually change sexual behavior. Because birth control is used so prominently across Western cultures, such apparently negligible differences don't appear to be enough for women to stop using contraceptive birth control.

One more difference between birth control users and nonusers is the aforementioned difference in affective jealousy. Women who are on birth control have reported experiencing higher overall levels of jealousy as compared to non-birth control users. Such a finding suggests that state jealousy must be hormone sensitive, and it has been deduced that estrogen levels are the culprit (Cobey et al. 2012). In other words, naturally cycling women experience more jealousy in their most fertile state, when estrogen levels are

high, while women on birth control experience a more steady yet consistently higher level of state jealousy throughout the entire cycle as compared to naturally cycling women in their non-fertile state. In addition, women, taking oral contraceptives who are paired, experience more jealousy than women taking oral contraceptives who are single. Overall, such an interesting finding posits that birth control alters mating intelligence and thus mating strategies in bizarre ways and perhaps plays a role in negatively impacting romantic partnerships.

An additional study conducted by Cobey et al. (2011) supported his previous findings on the relationship between estradiol levels and self-reported jealousy across women, by showing that elevated levels of ethinyl estradiol affect all types of operationalized jealousy. These jealousy types include reactive, possessive, and anxious jealousy. On top of that, the results remained significant even after controlling for relationships status, age, and mood. Lastly, this study found that there is no correlation between self-reported jealousy and progestin dosages, which further supports that estrogen and its synthetic counterparts are the jealousy-inducing culprits.

In the previous discussion, we have viewed birth control through the lens of hormonal contraceptives. Since birth control can be conceptualized as any method that prevents the conception of offspring in sexually active women, it's interesting to note how birth control might have been implemented in the ancestral landscape, before the rise of medicine. A fascinating theory to examine is the reproductive suppression hypothesis for explaining eating disorders (Wasser and Barash 1983). The reproductive suppression hypothesis posits that females suppress their reproduction when the current conditions are not in favor of reproductive success or offspring survival. That is, the female believes that the benefits of suppressing reproduction (i.e., depleting fat stores to the extent of stopping the ovulatory cycle, amenorrhea) outweigh the costs and that resources will be more plentiful and readily available in the future to assure reproductive success. This reproductive suppression is done through extreme dietary behaviors, and

preferring a thinner body ideal can be a way to manipulate the timing of reproduction.

In addition, a variant of this hypothesis was proposed by Surbey (1987). Surbey theorized that females can become anorexic as a way to stunt development. If a female is predisposed to mature earlier in a modern-day society that favors late maturers, anorexia is a way to change a female's natural developmental trajectory to one of a late maturer. Again, this is done by reducing fat through strict dietary behaviors. The benefit of late maturers in modern society is that it takes reproduction (i.e., reduces libido, attracts fewer males, induces amenorrhea) out of the equation when academic and professional success is more valued in the female's family. Overall, anorexia nervosa may explain an extreme method of birth control in ancestral times that has span of control in the modern landscape.

Conclusion

Birth control is a means of preventing unwanted pregnancy and is unique across modern human females. Birth control within itself goes against EEA causing a whole host of negative implications while defying the main objective for all living organisms to survive and successfully reproduce. Overall, much more research needs to be done on both the negative and positive implications of birth control.

Definition

The idea that the order in which a child is born within their family has influence over their development and personality.

Introduction

Birth order theory is the idea that the order in which a child is born within their family has influence over their development and personality. The theory was originally introduced by psychotherapist Alfred Adler in the 1920s (Eckstein and Kaufman 2012). Since Adler's initial research, others have attempted to make contributions to the theory. However, research has resulted in inconsistent findings attributed to confounding factors that arise from the multifactorial context of family environment, thus, leaving birth order's influence on development and personality a debated scientific topic.

Cognitive Development

Some studies suggest that cognitive development, such as intelligence, personality, and sexuality, can be affected by the order of an individual's birth within their family. Several of these previous studies have concluded that first-born children have slightly higher IQ's than later-born children (Belmont and Marolla 1974;

Rohrer et al. 2015; Silles 2010). Furthermore, IQ was found to decrease roughly 1.5 points per birth order position, and, overall, a randomly selected first born child is 52% more likely to have a higher IQ than a randomly selected second born child. This effect was found to be even greater when compared within the same family (Rohrer et al. 2015). Robert Zajonc attributed these effects to a model he first introduced, called the confluence model, which examines the development of individual differences in a social and environmental context. His research suggests that the lack of other siblings allows a first-born child to begin their development in an environment surrounded by adults and adult level intellect (Zajonc and Sulloway 2007). However, this model does not apply to only children and found that first-born children further benefit from the “tutor effect” in which older siblings help and teach their younger siblings, furthering their own proficiencies while doing so. Additionally, the model predicts “functional first-borns,” which are children who have a sibling at least 5 years older, that then benefits from the same or similar intellectual increases and may outscore the older sibling on intellectual testing (Zajonc and Sulloway 2007). The confluence model considers confounding and interrelated variables that influence an individual’s intellectual development in regard to birth order, taking into account factors such as the spacing between children and family size that influence the context of a child’s opportunities and resources for development within the family.

Researchers have found that similar social and environmental constructs surrounding birth order affect personality development. More current research regarding birth order and personality focuses on Frank Sulloway’s Big Five personality traits, which include extroversion, neuroticism, agreeableness, conscientiousness, and openness (1996). Sulloway took an evolutionary approach and suggested that personality was an adaptation to family dynamics (such as disparities in age, size, and power), which translate into personality differences between siblings that depend on birth order (Sulloway 1996). Rather than birth order itself being the

independent cause of personality, it is acclimatization to the surrounding environmental and social needs (that results from the order of birth) that shapes the individual. For example, since first-born children often take a parental or guiding role towards younger siblings, they tend to develop strong leadership qualities – making first-borns more controlling and dominating (Eckstein and Kaufman 2012). Because of their dominance, first-borns tend to be less agreeable, whereas later-born children tend to become more extraverted as they work to assert themselves. Being parental surrogates causes first born children to score higher on conscientiousness. First-borns and later-born children experience different kinds of openness to experience with first-borns scoring higher in objective intelligence and later-born children tending to be more imaginative due having to explore how they fit in a pre-existing family environment. Within the emotional stability category, first-born children are predicted to be more anxious and neurotic, whereas later-born children are predicted to be more depressed, self-conscious, and impulsive (Rohrer et al. 2015). Although there are various studies that explore the relationship between birth order and personality, many are confounded by the difficulty to control the variables studied that are statistically related to birth order (such as family size and social and economic demographics). Because of this, there are conflicted findings, especially in regard to personality and the Big Five, in which limited hypothesis have been proven true.

Beyond intelligence and personality, birth order has an effect on one’s sexual orientation as well, most notably with men via the fraternal birth order effect. This theory states that men have a greater probability of homosexuality the more older brothers they have, by an increase of 33% per each older brother. The same cannot be said for women, males with multiple younger siblings, or males with multiple older sisters. (Blanchard 2001; Bogaert 2003). Researchers believe this may be a byproduct of past human behavior that would inevitably reduce the probability of sons to compete among each other or with first or earlier born sons (Bogaert 2003).

Ultimately, this aspect of personality is influenced by birth order, but only under certain circumstances.

Physical Development

In some circumstances, birth order has effect on the physical development of humans. Similar to sexual orientation, having older brothers can affect the height of a man. This influence, again, may be a byproduct that shifts competition away from the oldest son (Bogaert 2003). Bogaert found that, when controlling for biological mechanisms, older siblings tend to be bigger than younger siblings (2003). Although, in regard to overall physical performance, later-born children tend to perform higher than first-born and only children. This higher performance is likely due to later-born children attempting to reach and surpass their older siblings' abilities and parents being more protective over first-born and only children (Krombholz 2006).

Pitfalls of Birth Order Theory

Despite the large number of studies surrounding birth order theory, birth order likely has less influence than suggested by pop psychology. Birth order can have some impact on an individual basis, but factors that are determined by birth order (such as family density), as well as other variables such as social and economic status influence an individual's development and personality more consistently. Additionally, patterns shown in many studies tend to not be replicable or consistent from study to study, making results inconsistent and unreliable.

Conclusion

The order in which an individual is born into their family and the influence that order has on one's development and personality has long been studied and debated. Researchers have found birth order to predict both cognitive and physical

development. However, these findings are limited and often inconsistent, oftentimes only strengthened by popular belief. More current research regarding birth order is taking into account confounding variables and focusing on how family environment and dynamics play a role in shaping an individual.

Birth Order and Parental Investment

Feifei Bu¹ and Frank J. Sulloway²

Synonyms

Family order effects; Sibling position effects

Definition

Parents may differentially invest limited resources in offspring who have a higher likelihood of survival, which is often older children; and equal division of parental investment across multiple children tends to have differing effects across firstborns, middleborns, and lastborns.

Introduction

During his visit to the Galápagos Islands in 1835, Charles Darwin was puzzled by the extensive diversity he observed among 13 species of Galápagos finches. These birds, he later realized, were actually members of a single, closely related avian group that had evolved its remarkable diversity through competition over time. Human siblings are a lot like Darwin's finches, as they also tend to diversify in various ways – for example in intellectual performance, personality, and social attitudes (Sulloway 2010). Some of this diversity among siblings is genetic. On average, full siblings share only half of their genes unless they are identical twins. Furthermore, even though siblings are brought up within the same family, they do not fully share the same family environment. And their differing family experiences are systematically related to birth order and parental investment.

From the perspective of evolutionary biology, Trivers (1972) defined parental investment as any

investment in individual offspring by a parent that increases the offspring's chances of survival and reproduction at the cost of the parent's ability to invest in other offspring. Parental investment can take various forms, including material resources such as food and other basic necessities; financial support for education and professional training; cognitive stimulation (for example, time spent reading to children or helping them with their homework); and interpersonal investment, such as attention, affection, and general encouragement (Hertwig et al. 2002). Intentionally or unintentionally, parents often invest unevenly in their offspring according to birth order. Such differences in parental investment are one of the mechanisms that drive offspring to compete with one another.

Sibling competition is particularly well documented among birds and mammals. When competing over valued resources, older offspring typically exhibit aggression toward younger ones, which, in extreme cases, can end in siblicide (Fig. 1). In an effort to diminish such fierce and generally costly competition, siblings tend to obey Charles Darwin's (1859) "principle of divergence." According to this principle, which has been widely validated through studies of other animal species, divergence is generally adaptive because it reduces direct competition for scarce resources.

Birth Order and Parental Investment, Fig. 1 A Verreaux's eagle chick has created a large wound in its one-day-old sibling. Sibling aggression in this species almost always leads to the death of the younger sibling (Photograph courtesy of Peter Steyn)

How Parental Investment Is Related to Birth Order

Before the beginning of the nineteenth century, nearly half of all children died before the age of 5, and even today infant mortality rates are still very high in some developing countries. When resources are limited, parents may invest more heavily in offspring who have a higher likelihood of survival and hence of passing their genes onto future generations. Older children are in a more favorable position as they have already survived some of the lethal diseases of childhood and therefore possess a greater prospect of future survival than do their younger siblings (Sulloway 1996). In addition, firstborns are often granted a greater role in perpetuating the family line, wealth, and traditions, especially in preindustrial societies. A good example is the custom of primogeniture, leaving inheritance to the oldest son, a practice that prevailed during much of the premodern period (Hrdy and Judge 1992). Apart from being favored by a greater share of family inheritance, firstborns – regardless of sex – are often given privileges through other social customs, including birth ceremonies, leadership roles, teknonymy (renaming a parent after a child), and having authority over their siblings in adulthood (Rosenblatt and Skoogberg 1974).

In modern society, as resources become more plentiful, parents tend to become increasingly egalitarian and to invest more or less equally in their offspring. Even when this is the case, however, the cumulative pattern of parental investment still tends to differ among siblings, and often produces inequality that is related to birth order (Hertwig et al. 2002). Because firstborns and lastborns both experience a period of exclusive parental investment when other siblings are not yet born or have grown up and left the home, they generally receive a greater share of resources compared with middleborns. Thus, the relationship between parental investment and birth order tends to be quadratic or U-shaped. Nevertheless, for those aspects of parental investment that are particularly important for human development during infancy or early childhood – for example, vaccinations and cognitive stimulation – lastborns

never obtain an advantage over middleborns. In such cases, an egalitarian motive among parents results in linear relationships between parental investment and birth order because each additional child dilutes the available family resources.

Theories about how birth order influences parental investment are well supported by empirical studies. Horton (1988), for instance, examined the relationship between birth order and nutritional status in 1,903 households in the Bicol region of the Philippines. He found that older children were more nutritionally advantaged over their younger siblings. Numerous other studies have shown that firstborns are more likely to receive vaccinations than are laterborns (Hertwig et al. 2002). A study of 14,192 children born between 1915 and 1929 in Sweden found that laterborn children had a considerably higher mortality risk compared with their firstborn counterparts (Modin 2002). Price (2008) reported that firstborns in two-child families received, each day, about 25 more minutes of quality time engaging with their parents compared with laterborns. In an investigation of 11,420 children of respondents from the National Longitudinal Survey of Youth 1979, Lehmann et al. (2014) found that mothers were more likely to breastfeed and to provide cognitive stimulation for their firstborn children. These empirical findings exemplify the linear relationship that is expected between birth order and some forms of parental investment. We need to bear in mind, however, that other forms of parental investment that are confined to adolescence and early adulthood have not been adequately investigated and, in some cases, are likely to manifest U-shaped relationships between birth order and parental investment.

Intelligence and Education

Birth order differences in parental investment can have profound influences on siblings in various ways. Abundant empirical evidence has shown that laterborn children tend to have lower IQs than their firstborn counterparts. For example, studies using large Norwegian administrative datasets ($N > 241,000$) have found that,

compared with secondborns, firstborns have IQ scores that were around 0.2 standard deviations, or 3 points, higher (Black et al. 2011; Kristensen and Bjerkedal 2007). In the same studies, these findings were confirmed by within-family comparisons, which cannot be confounded by socioeconomic or other differences in family background. Of particular interest in the Norwegian data is the fact that when birth rank changed as a result of the early death of an older sibling, the IQ scores of younger siblings increased, showing that IQ corresponds with functional rather than biological birth rank. Another large within-family study using Swedish administrative data ($N = 222,034$) also found that intelligence declined with increasing birth order (Barclay 2015). However, the overall evidence for the relationship of birth order to intelligence is mixed, as some studies have found no significant relationship. Most of these exceptional instances involve small sample sizes that often lacking adequate statistical power, or studies carried out with young children, for whom the influence of birth order is not yet fully manifested (Sulloway 2007; Zajonc and Sulloway 2007). Still, well-designed studies have also shown that lower-IQ parents tend to have larger families, and lower-IQ offspring, compared with higher-IQ parents (Rodgers et al. 2000; Wichman et al. 2006). This relationship has been ascribed to genetics and its influence on social status, which in turn correlates with family size. This confound has not always been adequately addressed in studies of birth order and intelligence, although it is not a relevant factor in within-family studies, such as the large Norwegian study conducted by Kristensen and Bjerkedal (2007).

Despite debate about birth order and intelligence, there is consistent evidence indicating that firstborns have an advantage over their laterborn siblings in educational performance and attainment. The following are just a few examples. In a study using sibling data from the UK, Bu (2016) found that firstborns not only had higher educational aspirations but also were more likely to gain post-sixteen qualifications allowing access to higher-level courses within the UK educational system. Using data that included the

entire Norwegian population, Black et al. (2005) also found a negative relationship between birth order and educational attainment. They reported that the difference in educational levels between the first and the fifth child in a five-child family was comparable to the black-white racial difference. Apart from the indirect influence on educational attainment through IQ, some birth order differences in education may also be explained by disparities in parental investment arising from differences in available financial resources as family size increases.

Personality and Social Attitudes

Birth order differences in parental investment, as well as closeness to parents, influence personality, self-esteem, parental identification, and the overall parent-child relationship. In one study, siblings who were favored by their parents, or who reported low levels of parent-offspring conflict, were more conscientious, agreeable, and extraverted; whereas those not favored by parents, or who reported high levels of parent-offspring conflict, were more open to experience and tended to identify less strongly with parental values and to question parental authority (Sulloway 1996, 2001). In a study asking participants to compare themselves with their siblings on various personality measures, Paulhus et al. (1999) found that firstborns were more conscientious and achieving; laterborns, by contrast, tended to be more agreeable, liberal, and rebellious. Such within-family studies are particularly instructive because there cannot be any confounds caused by uncontrolled socioeconomic disparities between different families. Sulloway (2001, 2010) performed a meta-analysis of 10 different within-family studies ($N = 7,218$), including that by Paulhus et al. (1999). These meta-analytic results showed that firstborns scored higher than laterborns on measures of conscientiousness, one aspect of extraversion (being assertive), and one aspect of neuroticism (anxiety). By contrast, laterborns scored higher on traits relating to agreeableness, most other aspects of extraversion, one aspect of neuroticism (self-consciousness), and several

indicators of openness to experience that are associated with unconventionality and open-mindedness. In another meta-analysis involving 8,340 participants in 24 different studies of athletic participation, Sulloway and Zweigenhaft (2010) showed that laterborns were more likely to engage in dangerous sports and to take more risks in professional athletics. For example, among 700 brothers who played Major League baseball in the United States, younger brothers were 1.7 times more likely to attempt to steal bases than their older brothers, and they were 1.4 times more likely to successfully complete a stolen base attempt.

Middleborns, who generally receive the least amount of parental investment, are reported to have lower self-esteem and to be more self-conscious compared with firstborns and lastborns (Kidwell 1982; Sulloway 2001). Studies have also shown that middleborns are not as close to their parents as are their siblings. For example, middleborns are less likely to turn to parents for emotional support in response to traumatic events (Rohde et al. 2003; Salmon and Daly 1998). This finding is a good example of the U-shaped relationship that is expected between birth order and some cognitive and behavioral outcomes.

Although within-family studies are nearly always supportive of birth-order differences in personality and social behavior, some very large between-family studies have found only small effects (Damian and Roberts 2015; Rohrer et al. 2015). Recent research involving more than 500,000 participants in an Internet personality survey using the Big Five Inventory has shown that reasonably impressive birth order effects exist in between-family samples when a variety of methodological precautions are observed, such as taking into account interactions between birth order and other demographic variables, including age, gender, sibship size, social class, race, and nationality (Sulloway et al. 2016). In addition, analyses need to be performed at the trait level, rather than at the broader dimension level to prevent differences in some aspects of personality from canceling themselves out (for example, assertiveness – a firstborn attribute, and being fun-loving – a laterborn attribute, would both be

scored under the dimension of extraversion). Some birth order effects are also relationship specific, in that the personality differences obtained when study participants rated only themselves were different from the results obtained when participants rated themselves and another person, which in turn differed depending on the specific identity of the other person being rated (for example, a sibling, a friend, or a romantic partner). One should also keep in mind that birth order is only an imperfect proxy, or mediator, of the real causes of sibling differences in personality. Three examples of important influences that are mediated by birth order are differences in parental investment, involvement in surrogate parenting, and physical size. Because researchers rarely examine these other causal variables, investigations typically overlook influences on personality that are revealed by more carefully designed approaches to the study of “family niches” (Sulloway 2001; Sulloway et al. 2016).

The influence of parental investment on parental identification and the parent–child relationship extends to social attitudes. More specifically, higher levels of parent–offspring conflict are associated with more liberal social attitudes among offspring (Sulloway 1996). In a study of 569 Chinese Tokok families in Indonesia, older siblings were more obedient to their parents’ wishes and more conservative, socially and politically, compared with their younger siblings (Skinner 1992). Among Japanese-American immigrant families, Manaster et al. (1998) found that firstborns were more likely than laterborns to carry on family traditions, including speaking the Japanese language, and were also more likely to be political and religious conservatives. In a meta-analysis of 20 previous studies, Sulloway (2001) reported that laterborns were 20 % more likely than firstborns to endorse a liberal political viewpoint, which was roughly equivalent to the gender gap in voting behavior in the United States. These results are consistent with another series of studies based on historical data, which found that laterborns were twice as likely as firstborns to support radical revolutions in science and various social and political domains (Sulloway 1996).

Conclusion

In sum, considerable theoretical and empirical research has shown that parents invest unevenly in their offspring in relation to birth order. As a result, siblings with differing birth orders tend to compete for parental favor and to diversify in various ways, including in their intelligence, education, personality, parental identification, and social attitudes. Under most circumstances, birth order effects are relatively modest, but it is likely that these effects will be greater in magnitude whenever they have been elicited by an appropriate stimulus that taps patterns of behavior learned in childhood. Parental investment is just one among several potential mechanisms that generate and explain these observed birth order differences. Much still remains to be learned about other psychological mechanisms that underlie sibling differences. One conclusion, however, is now well established, namely, that the family is not a uniform environment for offspring, and differences in within-family experiences cause siblings to diverge in a multiplicity of ways.

Definition

In medieval English, the word “sibling” was used to refer to all relatives or “kin,” but in the

early twentieth century, anthropologists defined siblings as individuals who share one or both biological parents. However, the rise in new and complex family forms has broadened this definition to include children who grow up in the same family (e.g., stepsiblings, foster siblings, adopted siblings) and who are biologically related but live in different families, as in the case of “donor siblings” conceived using the same gamete donor. Adding to this complexity, definitions of siblings are even broader in non-Western cultures and can include all children living in a community.

Introduction

Children develop social and cognitive skills through repeated, meaningful interactions with those with whom they share intimate close relationships. As the most enduring of all close relationships, sibling relationships have unique potential not only to influence children's development but also to contribute to well-being across the life-span. Alongside this longevity, three other unique features underpin the importance of sibling relationships. First, unlike friendships, sibling relationships are involuntary. Thus, while young children quickly learn to refrain from showing negative behaviors toward friends who might otherwise simply walk away from the friendship, they can be unrestrained in their expressions of negative emotions toward siblings. As a result, sibling interactions often have a love-hate “no-holds barred” quality. Although sibling conflicts can be exhausting for parents, they also provide fertile contexts for learning about differences in points of view and for developing effective means of repairing interactions after a disagreement. A further consequence of the involuntary nature of sibling relationships is that, for mixed gender sibling dyads, intimacy can cross the gender barrier that segregates peer interactions in the playground. For many children then, siblings provide unique opportunities to become familiar with the opposite sex.

A second distinguishing characteristic of sibling relationships is that they are “diagonal” in

nature. That is, within the sibling relationship, the companionship, fun shared pretend play, and reciprocity that characterize close relationships between children are combined with vertical elements of parent-child relationships (e.g., caregiving, pedagogy). Reflecting this diagonal structure, siblings often fulfill many roles, for example, as playmates, caregivers, rivals, and role models. While effects of sibling role models have largely been studied in relation to risk-taking behavior (e.g., early sexual activity, drinking, substance use – for a review, see McHale et al. 2012), they are also evident in relation to prosocial behavior (e.g., Pike and Oliver 2016). Note also that while the age gap that underpins the diagonal nature of early sibling relationships becomes less significant as children grow up, the diagonal quality of sibling relationships may persist as older siblings continue to forge a path for younger siblings, in negotiating their rights and responsibilities as adolescents and in coping with external stressors such as exams, leaving home, and becoming independent.

The third feature of sibling relationships that deserves note is their interplay with other close relationships. For example, sibling conflict is linked to parent-child and marital conflict and is also exacerbated by parents' differential treatment of siblings (e.g., Brody 1998). Indeed, accounts of sibling rivalry date all the way back to biblical times (e.g., Joseph and the coat of many colors given to him by his father, which almost drove his brothers to fratricide). Thus sibling influences can be indirect as well as direct, with children closely monitoring parents' interactions with siblings for signs of favoritism and unequal treatment or unhelpful parental comparisons of siblings leading to poor adjustment (Buist et al. 2013). Sibling relationships also intersect with children's friendships. Echoing the importance of sibling relationships as a forum for children's learning to form and maintain harmonious interactions, longitudinal evidence shows that children exposed to persistently high levels of sibling conflict (from ages 3 to 6) were, at age 6, especially likely to display bullying behavior toward unfamiliar peers (Ensor et al. 2010). Studies of adolescent siblings also indicate that older siblings can act as gatekeepers

to deviant peer groups (e.g., Ardelet and Day 2002). Thus, through interactions with both parents and friends, siblings can exert indirect influences on well-being and adjustment.

As noted below, evolutionary perspectives hinge on the premise that studies of nonhuman species can yield insights into the origins of human behaviors, such as sibling cooperation. In this regard, while studies of birds have informed accounts of sibling competition (as exemplified by the behavior of the baby cuckoo), studies of mammals have also been more informative with regard to the evolutionary advantages of sibling cooperation. In particular, mammalian offspring spend much longer in close contact with the mother, and hence siblings can influence development postnatally as well as in utero. Thus, alongside the obvious competition between siblings for resources, among mammalian species, the presence of a sibling may be advantageous prenatally (e.g., by jointly producing sufficiently strong hormonal signals to maintain a pregnancy), postnatally (e.g., by increasing the efficiency of thermoregulation), and in adult life (e.g., by forming coalitions for hunting or defense) (for a review, see Hudson and Trillmich 2008). While few studies of sibling relationships in nonhuman primates have adopted longitudinal designs, a 10-year study of male chimpanzees showed that, compared with unrelated males, maternal brothers showed more equitable levels of grooming and more stable bonds (Mitani 2009), indicating that sibling relationships contribute to group cohesion. Thus, from earwigs to chimpanzees, animal studies confirm the potential benefits as well as costs of growing up with siblings.

Evolutionary Theories of Family Relationships

Evolutionary theory suggests that psychological processes have evolved due to natural selection, as a means of increasing reproductive fitness. Several evolutionary theories may help make sense of sibling dynamics (for a more in-depth review, see Pollet and Hoben 2011). Hamilton's

(1964) theory of the evolution of altruistic behavior suggests that individuals will engage in behaviors that do not improve their own reproductive fitness if these behaviors increase the reproductive fitness of a genetically related individual and thus confer an indirect fitness benefit to the donor. This theory is often expressed as an equation $Br > C$, where B is the benefit of the behavior to the recipient, r is the degree of genetic relatedness between the donor and the recipient, and C is the fitness cost to the donor. According to this equation, altruism will occur if the benefit times the relatedness is greater than the cost to the donor. Importantly, this theory suggests that individuals are more likely to engage in prosocial behavior toward siblings than toward unrelated individuals and that prosociality toward siblings should depend on the level of genetic relatedness. For example, prosociality among full siblings should be greater than among half-siblings, which should in turn be greater than among stepsiblings.

Another relevant evolutionary perspective is parent-offspring conflict theory (Trivers 1974). According to this theory parents are expected to invest the maximum resources available in their offspring even if this is detrimental to themselves or to future offspring. At the same time, offspring may try to obtain more resources than the parent is able to give to maximize their reproductive potential, leading to a conflict between parent and offspring. An implication of this theory is that sibling competition for parental resources may be beneficial for offspring to maximize their individual reproductive fitness, even if this is to the disadvantage of their parents and siblings. In the next sections, sibling conflict and competition are explored in relation to these evolutionary accounts.

Sibling Conflict

Conflict is a hallmark of sibling relationships and as discussed above is prominent in literary and biblical accounts of sibling relationships. Data from naturalistic observations suggest that in interactions between young siblings, conflict is frequent, occurring on average 3.5 times an hour (Kramer et al. 1999). Sibling conflict is often

thought of as a “horribly normal” part of childhood in Western cultures, but in non-Western cultures, sibling conflict may be less prominent (e.g., White and Hughes 2017). While sibling conflict may be troublesome for parents, theorists have suggested that it may provide an important context for learning about others’ thoughts and feelings and may therefore contribute to the early advantage in social understanding observed for siblings compared with only children (Devine and Hughes 2018). However, extreme levels of sibling conflict, particularly physical violence, may provide a training ground for aggressive behavior in other contexts. Although this chapter will focus on human siblings, sibling conflict is prevalent among animals. For example, sibling fighting over access to food is common in many species of birds and may even lead to siblicide (for a detailed exploration of family conflict among animals, see Mock 2004).

As noted above Trivers’ (1974) theory suggests that sibling conflict arises because siblings are direct rivals for parental resources, a view that is shared with many psychoanalytic perspectives of sibling conflict. Michalski and Euler (2007) suggest that children may actively seek to obtain more parental resources by manipulating their parents’ perceptions of their needs. For example, they argue that reports of firstborn children showing developmental “regressions” (e.g., waking up in the night having previously slept through) following the birth of a new sibling may reflect a strategy to gain a larger share of parental resources now that these resources are being divided with another child. Children are likely to become less reliant on parental resources as they grow older and particularly when they leave the parental home and start their own families. One might expect, therefore, that sibling conflict should reduce as children age. Empirical studies of sibling relationship quality over childhood provide some evidence for a decrease in sibling conflict in adolescence, but the lack of long-term longitudinal studies of sibling relationships, particularly those spanning the transition to adulthood, means it is unclear how levels of sibling conflict change from childhood to adulthood (White and Hughes 2017).

What factors influence sibling conflict? According to Trivers' (1974) theory, sibling conflict will depend on the degree to which there is competition for parental resources. Therefore, higher levels of sibling conflict might be expected in larger families (in which there are more siblings competing for a given amount of parental resources) and in families with lower socioeconomic status (in which parental resources are more limited). The few studies that have examined links between sibling relationship quality and family size or socioeconomic status have generated mixed results (see White and Hughes 2017), perhaps reflecting the effect of other influences on sibling conflict or differences in methods of measuring sibling interactions.

Sibling conflict should also be related to the degree of genetic relatedness between siblings, because siblings who share two biological parents are competing more directly for parental resources than half-siblings or stepsiblings. Support for this proposal comes from a study by Michalski and Euler (2007) in which university students reported more current and prior conflict with full siblings than with half- or stepsiblings. Furthermore, students reported an age-related decline with full siblings and half-siblings (but not stepsiblings). These findings suggest that genetic relatedness plays a role in competition for parental resources and also highlights the importance of examining trajectories of sibling conflict over time separately for different types of siblings.

Sibling Cooperation

Comparative, developmental, fossil, and neurobiological evidence has led theorists to argue that late human evolution was dominated by selection for intragroup prosociality over aggression – that is, the “survival of the friendliest” (Hare 2017). Most individuals encounter their first opportunities for cooperation in the context of sibling interactions; understanding sibling cooperation therefore holds the promise of identifying processes that make us uniquely human.

Sibling cooperation takes many forms, of which perhaps the most obvious is turn-taking.

Learning to take turns with a prized object (e.g., a new toy) is doubly rewarding, in that it not only minimizes the distress associated with disputes but also increases enjoyment by maximizing the time children spend actually playing. Parents are therefore highly motivated to teach children to share their possessions with their siblings. However, turn-taking is an important form of cooperation even when there are no prized objects at stake. For example, games of shared fantasy hinge on all actors playing their part and so require the coordination of different points of view (e.g., on whether a broomstick will fly to the moon or another destination). Cooperating with a sibling therefore provides valuable opportunities to practice mentalizing skills and so provides a likely explanation of why the presence of siblings is associated with accelerated development of “theory of mind” skills (Devine and Hughes 2018). Direct support for this view comes from the finding that differences in older siblings' cognitive sensitivity (i.e., the ability to provide information in a helpful and accessible manner) help to explain variation in the extent to which young children's theory of mind development benefits from the presence of a sibling (Prime et al. 2016).

Helping is another obvious example of sibling cooperation. As detailed below, the asymmetrical nature of sibling relationships means that it is more usual for an older sibling to help a younger sibling (e.g., in acquiring a new skill, or solving a problem). However, even very young toddlers take delight in finding ways to be helpful, and so helpful behaviors can be reciprocal within the sibling relationship. Recently, the power of a developmentally sensitive within-family design has been used to investigate birth order effects on preschool children's cooperative abilities. Specifically, in a study involving a socio-demographically diverse sample of 144 Canadian families, Prime et al. (2017) found that youngest children displayed the highest levels of cooperation while middle children were also advantaged but only if their siblings were prosocial. Here it is worth noting that findings from a study of 524 pairs of 3- to 8-year-old twins show that individual differences in spontaneous instigation of cooperation with a sibling reflected

environmental rather than genetic factors (Lemery and Goldsmith 2003). Understanding how structural factors (e.g., birth order) and social factors (e.g., relationship quality) interact to enculturate children into adopting cooperative attitudes is an important direction for future research.

As for turn-taking, helping does not require a physical task or problem but can also be manifest at a mental level, through the formation of alliances in polyadic conflict (Persram et al. 2017). Importantly, such alliances are most likely when a sibling faces an external threat. Despite their differences, siblings can usually be counted upon to look after each other. Empirical evidence to support this view comes from studies that portray siblings as supportive fellow travelers through stressful times, such as family change (e.g., Kempton et al. 1991). Literary examples of sibling cooperation also abound. For example, in Jane Austen's *Pride and Prejudice*, Elizabeth and Jane have a very low opinion of their flighty younger sister, Lydia, and yet step in to the parental role by striving to protect her reputation when she elopes with the perfidious Wickham. Returning to the self-domestication hypothesis (i.e., that late human evolution can be described as a "survival of the friendliest"), sibling alliances may therefore provide the building blocks of societal norms that underpin civilization.

Findings from animal research lend weight to the argument that sibling cooperation is an ancestral behavior that can be retained to compensate for insufficient levels of parental investment. For example, studies of earwigs indicate increased sibling cooperation (as assessed by food transfer) in the context of low maternal food provision (Kramer et al. 2015). While a parallel between the novels of Jane Austen and the results of research on earwigs might seem far-fetched, the importance of this context of "insufficient parental investment" deserves note: if their parents had been more effective as figures of support, would the Bennett sisters have shown such high levels of sibling cooperation? Highlighting the potential importance of siblings as figures of compensatory support, elevated levels of caregiving between siblings are often reported in studies of sibling relationships in traditional non-Western cultures,

in which parents are required to work long hours away from home during the day (e.g., Cicirelli 1994). Against this view, however, is the positive relationship between maternal warmth and children's prosocial behavior, widely reported in studies involving within-population comparisons (e.g., Dunn 1998). In other words, studies of individual differences suggest direct "spillover" effects between parent-child and sibling relationships. Support for this alternative view also comes from the finding that fathers' active involvement in childcare increases the likelihood of preschoolers' displays of affection and concern toward infant siblings (Song and Volling 2015). Clearly then, more work is needed to understand the variety of ways in which family processes influence sibling cooperation.

Asymmetry in Sibling Relationships: Origins of Birth Order Effects

A key area of study within the sibling literature has been the effect of birth order, that is, the ordinal position an individual sibling holds within the family. In the next sections, the effects of birth order on parenting, academic achievement, and personality are discussed, but first the origins of sibling differences are explored. An important feature of sibling relationships (with the exception of twin relationships) is the age gap between siblings. In childhood this age gap is associated with a disparity in social, emotional, and cognitive abilities that promotes an asymmetry in roles within sibling interactions. In childhood, older siblings typically take the lead in sibling interactions as initiators of both positive and antagonistic behavior and also spontaneously engage in teaching and caring for their younger sibling. Younger siblings are keen imitators of their older sibling and are active learners in teaching situations.

Recent research suggests that the asymmetry in sibling roles within interactions may have implications for children's adjustment. Using data from the Avon Longitudinal Study of Parents and Children, Pike and Oliver (2016) examined the associations between children's prosocial behavior and behavior problems and the quality

of their sibling relationship over a 3-year period beginning when the younger sibling was 4 years old. Their findings showed that older siblings' behavior was a stronger predictor of younger siblings' behavior across time than the reverse, and this was true for both prosocial behavior and behavior problems. Moreover, older siblings' prosocial behavior was more strongly associated with positivity in the sibling relationship than younger siblings' prosocial behavior, both cross-sectionally and across time, although a similar pattern of findings was not found for behavior problems and sibling negativity. These findings suggest that, reflecting their dominance within sibling interactions, older siblings have a dominant influence on individual behavior and sibling relationship quality across time.

The age gap between siblings also contributes to children's differential experiences of the same family. For example, siblings experience key family events at different times and receive differential treatment by parents and other family members because of their birth order, as well as other factors (e.g., gender, temperament). These non-shared environmental influences account for findings that siblings within the same family are often very different from one another (Plomin et al. 2001). Non-shared environmental influences may also occur because children seek to differentiate themselves from their sibling by developing distinct interests and personal qualities and seeking out different "niches" within the family. This process of sibling "de-identification" was first described by Adler who proposed that sibling rivalry for parental attention and family resources arose as a means for siblings to overcome feelings of inferiority. According to Adler, de-identifying with a sibling provided a way to overcome feelings of inferiority and thus reduce sibling conflict. However, empirical support for a link between de-identification and reduced sibling conflict has been mixed (Whiteman et al. 2007).

Birth Order and Cognitive Performance

The study of birth order and cognitive performance began with Francis Galton's investigation

of the characteristics of fellows of the Royal Society, in which he observed that firstborns were overrepresented among these "men of science". Nearly 150 years later, interest in birth order as a predictor of achievement or cognitive performance remains prominent in the fields of psychology and sociology. Three main theories have been proposed to account for effects of birth order on academic achievement. These theories also explain effects of family size, which is frequently conflated with birth order, but in the interest of brevity, only birth order effects will be discussed here. The resource dilution hypothesis (Blake 1981) suggests that children's achievement relies on investment of time and money from parents. These resources are finite such that the addition of each new child in the family results in a reduction of resources available to any one particular child. This theory suggests that within a given family size, firstborn children will outperform later-born children because they have spent more time as the sole recipient of parental resources. Moreover, youngest children are likely to outperform middle children as they have a period of time alone with their parents after the other children have left home. A further corollary of this theory is that birth order effects are likely to be most marked in poorer families where parental resources are more limited.

In contrast, the "confluence" model (Zajonc and Markus 1975) suggests that two competing processes contribute to children's academic achievement: the "intellectual environment" within a family, which is based on a weighted average of the intellectual abilities of all members, and the learning opportunities provided by teaching a younger sibling. According to this account, birth order effects are not static but vary over the course of a child's lifetime and depend on the structure of the family. For example, in a two-child family, when comparing children's academic achievement at the same age, the firstborn will have an advantage at a very young age (i.e., before the second child is born) and then again in adolescence when the child has gained from opportunities to teach their sibling. Finally the admixture hypothesis suggests that genetic or environmental differences between

families, rather than within-family processes, give rise to birth order effects on academic achievement (e.g., Rodgers et al. 2000). For example, birth order effects may arise because of differences in family size based on parental intelligence or socioeconomic status.

Empirical studies examining these three accounts of birth order effects on achievement have been mixed. For example, using a national representative cohort study, Kanazawa (2012) showed that birth order was not linked to children's performance on cognitive tests once family size was controlled statistically, supporting an admixture hypothesis. In contrast, in a similar-sized study, Iacovou (2008) showed that middle- and youngest-born children had lower academic achievement than firstborn children, and the size of these effects varied with family size. The author interpreted these findings as support for the confluence hypothesis whereby for youngest children the benefits of having time with just their parents at home and the lack of opportunity to teach younger siblings cancel each other out so that youngest children's achievement is similar to that of middle-born children. However, this hypothesis is difficult to test empirically, highlighting the methodological challenges in understanding the effects of birth order on academic achievement.

Birth Order and Personality

The notion of birth order effects on personality stems from psychoanalytic perspectives on the sibling relationship and has long held traction in popular culture. Sulloway (1996) developed an evolutionary niche-picking model to explain birth order effects on personality, suggesting that traditional patterns of parental investment, in which parents typically invest more in first-born sons (the heir) than in later-born sons (the "spare"), give rise to different strategies to increase parental investment. Specifically, Sulloway (1996) argues that firstborns, who are traditionally their parents' main heir, display personality characteristics and hold beliefs and attitudes that mirror those of the parents, while

later-born children are more likely to hold beliefs, attitudes, and personality characteristics that differ both from their parents and from their older sibling. Using historical data about scientist brothers and their willingness to subscribe to new scientific theories, Sulloway (1996) suggests that firstborn siblings are more likely to conform and accept the status quo, whereas later-born siblings are more likely to rebel and show creativity. Sulloway (1996) also suggests that older siblings are more likely to use physical power to assert themselves, leading to lower agreeableness, but may attempt to please their parents by caring for younger siblings, leading to higher levels of conscientiousness. In contrast, later-born siblings may rely on social support to assert themselves and thus become more extraverted and may be more open to experiences because they have had to find innovative ways to find a family niche and differentiate themselves from their siblings.

This niche-picking hypothesis has attracted considerable research attention, but several large-scale well-controlled studies have failed to replicate Sulloway's findings. In a representative US sample of 377,000 high school students, Damian and Roberts (2015) found that, after controlling for effects of age, sex, sibship size, socioeconomic status, and family structure, the average association between personality characteristics and birth order was so small as to be negligible. Rohrer et al. (2015, 2017) confirmed these findings in two further studies that used both within- and between-family approaches to analyze birth order effects conducted and found no meaningful effects of birth order on either broad personality characteristics or narrower personality traits. Rohrer et al. (2015) suggest that these findings may indicate that birth order effects may be observed in behavior within the family but may not influence behavior outside of this context or that birth order may influence aspects of personality into which most people have little self-insight.

Birth Order and Parenting

As discussed above, the resource dilution model also predicts that parents' psychological resources will be diluted with each new child, such that

parental warmth and sensitivity may be reduced for later-born children. However, this hypothesis has been challenged in several ways by empirical evidence from longitudinal studies. For example, using growth curve models to analyze four waves of data on parenting practices gathered biennially between 1994 and 2000 from a nationally representative sample of over 2000 Canadian mothers of 2- to 5-year-olds living in continuously intact, two-biological-parent households, Strohschein et al. (2008) concluded that increased family size led to the reallocation, rather than the dilution, of parenting resources. Likewise, in a 5-year longitudinal study of 201 sibling pairs, Shanahan et al. (2007) reported that age-related drops (from ages 7 to 19 years) in experience of parental warmth were sharper for firstborn children than for later children, suggesting a “learning from experience” effect, rather than a “resource dilution” effect.

Research on earlier stages of parenting provide mixed support for this “learning from experience” hypothesis. In a study of 364 Dutch families with two children seen at home around the younger child’s first, second, and third birthday, Hallers-Haalboom et al. (2017) found no association between changes over time in parental sensitivity to each child and concluded that rather than being affected by experiences with the firstborn, sensitivity toward the second-born is driven by children’s unique characteristics and developmental stages. In contrast, Bernier et al. (2018) have argued that effects of birth order and sibship size on maternal sensitivity are likely to vary for specific components of sensitivity and depend on mothers’ own attachment relationships. Specifically, while maternal attunement and cooperation did not differ by birth order, mothers who had an insecure relationship with their own caregiver appeared less available and positive toward their later-born children than toward their firstborn child, perhaps because the competing needs of different children had a stronger impact on their cognitive flexibility and well-being.

Together, the four sets of findings outlined above highlight the dangers of oversimplifying accounts of how birth order might affect parent-child interactions. Parents expecting a second child are often amazed to discover that, despite

their all-consuming love for their first child, they can also tumble headlong in love with a second child. By analogy, the resource dilution hypothesis is based on the false premise that psychological resources are finite: when faced with competing demands for attention, many parents are able to deploy creative strategies to ensure that they can meet the needs of all their children. However, as demonstrated by the moderation effect reported by Bernier et al. (2018), this ability to respond calmly and flexibly is likely to hinge on parents’ own well-being and security of attachment.

Conclusion

In this short chapter, we have tried to do justice to the rich learning opportunities that result from the enduring and familiar nature of sibling relationships, as well as from the multiple intersections between interactions with siblings and within other close relationships. Three aspects of evolutionary theory were noted: (i) the salience of genetic relatedness as a context for prosocial and conflict behavior (giving sibling relationships their well-recognized “love-hate” quality); (ii) parent-offspring conflict, which can lead to alliances between siblings and cooperation in the context of low parental investment; and (iii) the importance of intragroup cooperation within late human evolution, leading to a “survival of the friendliest” in which, once again, sibling interactions provide a fertile ground for developing key skills for adult success. Having described the different forms of sibling conflict and cooperation, we finished this chapter by considering birth order effects on cognitive achievement, personality and parenting. Key mechanisms underpinning potential birth order effects include not only negative consequences of resource dilution but also positive consequences of parents learning from experience or older siblings gaining skills by taking on caregiving or teaching responsibilities. Adding to this complexity, birth order effects are temporally dynamic and may also covary with other contrasts associated with family size (e.g., education, affluence). As a result, birth order effects are typically small in magnitude,

restricted to within-family contexts, or moderated by structural or interpersonal factors (e.g., the age gap between siblings or parents' own emotional security) that affect parents' ability to be flexible in sharing their attention between children. Such effects are therefore likely to be eclipsed by the powerful nature of siblings' direct influences upon each other, be that as sparring partners and rivals, or as sources of companionship, affection, and support.

Birth Position

► Birth Spacing and Birth Order

Birth Spacing and Birth Order

Erin Wood and Shelia M. Kennison
Oklahoma State University, Stillwater, OK, USA

Synonyms

Birth gaps; Birth interval; Birth level; Birth position; Child spacing

Definition

The amount of months or years in between consecutive siblings within a family; the biological or functional position in which an individual resides in a group of siblings with a family.

Introduction

Since the biblical times of Cain and Abel, there have been noted differences between individuals from both within and outside of a family unit due to their birth position. Professionals have likened differences between siblings to Darwin's theory evolution because they believe that individuals will try to differentiate themselves from siblings to obtain the most parental resources for survival (Sulloway 1996).

Differences had been noted between siblings in a family depending on birth order as early as 1874 with Sir Francis Galton; however, the majority of birth order research did not begin until after 1928 – the year when Alfred Adler hypothesized about personality differences between birth order cohorts. More recent birth order research has not only focused on personality but it has also focused on individual factors such as: intelligence, parental involvement, sexuality, etc. Since 1928, there have been many disagreements within the academic community about the validity of research results claiming differences in personality or other individual factors between birth orders. Many of these opposing arguments have focused on the varying amounts of children and spacing of children between families not being accounted for in prior research (Ernst and Angst 1983). Recent studies that control for various social factors, however, have been used to combat some of these complaints – showing potential validity of birth order effects.

Although research has been conducted on the effects of birth order on various individual factors, an individual must first understand the effects of birth spacing before inferences on birth order effects can be made. This is because the spacing between the birth of siblings can be used to

increase or decrease competition – ultimately effecting the development of social behaviors.

Birth Spacing, Birth Order, and its Influence On Child Personality, Intelligence, Sexuality, and Health

In 1874, Sir Francis Galton stated his observation that fellow members of his academic community were more likely to be the eldest born child in their family than any other nominal birth order position. There are five nominal birth order positions commonly recognized by researchers: first-born, second-born, middle-born, last-born, and only-born.

Though the positions of the first-born, last-born, and only-born are generally salient and agreed upon, there are many discrepancies between whether an individual should be placed within the nominal position of second-born or middle-born based on where they lie in their sibling cohort – also known as a sibship. For some researchers, being labeled as a “second-born” can indicate the younger sibling in a two-sibling dyad (Price 2007) or can be used interchangeably with “middle-child” for sibships of three where they are neither the youngest nor the eldest (Saroglou and Fiasse 2003). In conversation, second-born can also be used to describe the second-born child in a sibship of four or more children. And, lastly, any child that is in a sibship that is not the first-born often falls under the umbrella term “later-born” – meaning that they were not the first child born in the family.

Also, an individual's birth order can be used to describe both their biological and functional birth order within their family. According to Sulloway (1996), an individual's biological birth order is a static descriptive determined by the order in which they were born – independent of the death of another sibling or other changes in family structure. Oppositely, functional birth order is an unfixed descriptive used to describe where an individual lies within a sibship depending on the amount of living individuals in the sibship. Due to advances in modern medicine in industrialized

societies, an individual's functional birth order is less likely to change due to death of a sibling (McLanahan 2004). Rather, modern changes in functional birth order occur due to changes in family structure such as the adoption of a non-biological sibling or a parent remarrying an individual with children from a prior marriage or union (Sulloway 1996; McLanahan 2004).

Because of the varying dynamic between biological and functional birth order effects, there have been many branches of research conducted on how birth order effects individual factors such as personality, intelligence, sexuality, and mate preference and how they can be exacerbated by the spacing between births of siblings. However, for the purposes of this entry, birth order will be discussed as if it pertains to both a child's biological and functional birth order as observations have shown that individual will most likely adapt to their functional birth order if there is a change early in life (Sulloway 1996).

Birth Spacing, Fertility, and Child Outcome

In developed nations, there has been a dramatic decrease in the amount of children produced by mothers over the past 50 years. Partially explained by the increasing availability and social acceptability of oral contraceptive pills, women today are having two to three less children than their 1970 counterparts with the average mother today having an average of 2.5 children in comparison to the 5.1 children of years past (Feldman et al. 2009). Some researchers, such as Kanazawa (2012), report the conscious decrease in the number of children born by each mother "evolutionarily novel" because it contradicts the notion made by many Darwinian evolutionary theorists that an organism must produce as many offspring to be seen as "fit" (p. 1161). If a woman was to maximize her reproductive potential, she could become pregnant within 8 weeks of giving birth – depending on maternal health or nursing practices (Bereczkei 2001).

However, as briefly indicated above and discussed further in depth in future sections, human reproduction rates have not always contradicted the Darwinian "survival of the fittest" theories. In previous centuries, due to high

child mortality rates perpetuated by unadvanced medical practices, families would have large amounts of children in them to ensure that at least one child would reach reproductive maturity to propagate their families genes (Sulloway 1996). Today, the practice of bearing multiple children has become outdated due to advances in medicine which have drastically reduced child mortality rates. Now, parents are actively limiting the number of children they have to ensure that they have the enough resources (such as money, attention, and time) to care for each child they bring forth (Sulloway 1996; McLanahan 2004). By having enough resources, parents are able to ensure that their children not only reach reproductive maturity but they are also able to become productive members of society (McLanahan 2004).

Though there are dramatic differences in the amount of children born per family when comparing the families of today with the families that lived centuries prior, there are actually few differences in the spacing of children. According to the World Health Organization, women should not actively try to become pregnant within 24 months of giving birth (Hambimana-Kabana et al. 2016). If a mother is to become pregnant prior to 24 months after giving birth, there is a larger risk that she will have a miscarriage or stillbirth if she is in a developing country because she will not have the necessary medical services available (Ahmed et al. 2015; Hambimana-Kabana et al. 2016). By increasing the time between births, mothers will be able to decrease competition to recover and restore their health after enduring childbirth (Lee 1980; Bereczkei 2001). However, in a review conducted by Conde-Agudelo et al. (2012) it has been indicated that while increasing the time between births might buffer the competition between siblings, very brief spacing as well as extremely long spacing between children could also have aversive influences on the health of both the mother and offspring.

Mother's with shorter intervals in between consecutive births might have decreased health as the demands of caring for a newborn (i.e., nursing) might cause nutrient deficiencies which can lessen the overall health of the mother.

These negative effects are exacerbated when the mother conceives a subsequent child before she is done nursing as she will now have a fetus and an infant vying for her nutrients (Conde-Agudelo et al. 2012). Further, maternal vitamin deficiencies which can occur after the birth of an offspring, if not restored, can cause considerable negative detriments to subsequent offspring (Conde-Agudelo et al. 2012; Fotso et al. 2013). In regard to the effect short intervals between births can have on child health and survival, in a research conducted on children born in Africa by Fotso et al. (2013) found that children who had an older sibling born less than 18 months before them but they themselves are not the last-born were more likely to die in infancy. Similar to children of mothers born with folate vitamin depletion, research provided in the review conducted by Conde-Agudelo et al. (2012) indicates that extended gaps between children (i.e., more than 5 years) is attributed to negative offspring outcomes (birth weight, preterm birth, etc.) and maternal outcomes (preeclampsia, labor dystocia).

In traditional hunter-gatherer societies, women might increase the spacing between births to not only decrease the competition between siblings for resources but to decrease the amount of energy they expend while caring for the child. For !Kung women, longer birth intervals are encouraged to reduce the workload as !Kung women would physically carry their children while gathering food (Lee 1980; Jones 1986). Because !Kung women traditionally carried their children until they reached 4 years of age, having multiple children under the age of four would increase the energy expenditure of the mother – ultimately decreasing the total amount of resources available to the children (Lee 1980). Lee (1980) continues to state that, in a society that is no longer solely dependent on hunting and gathering for survival, spacing might no longer be necessary to survival; however, spacing might still be necessary to ensure that each child reaches their developmental potential.

The statements made by Lee (1980) might be best explained by Trivers' (1974) *Parent-Offspring Conflict*. With *Parent-Offspring*

Conflict, it is thought that for all mammals – not just humans – parental investment is higher at the beginning of the offspring's life than when the offspring is more independent. This is posited to be because the pressure and demands of the offspring in its early life does not surpass what the mother is able to provide or impact her future reproductive status but the demands of an older offspring might. Mother's will then begin to wean her child by no longer actively providing milk to her child and might reject the advances made by her offspring to nurse. This timeline provided by the *Parent-Offspring Conflict* (Trivers 1974) can further support the research supporting longer birth intervals between subsequent births as it ensures that parents will not have conflicts with multiple offspring at one time.

Research has indicated that, when comparing subsequent births following the birth of a first-born female or male child, there are larger spaces following the birth of male children than female children (Blanchard and Bogaert 1997). Blanchard and Bogaert (1997) continue to create three explanations for the findings. The first explanation, similar to statements made by Sulloway (1996), is that there has historically been a higher social value placed on male children when compared with female children – making a parent who gives birth to a female child more likely to have smaller birth intervals as they try to bear a son. Oppositely, the second explanation created by Blanchard and Bogaert (1997) might discredit their previous explanation by stating that space between male births might be more explainable by the potential negative reaction of the mother's immune system in reaction to the antigens produced by the male fetus which could cause a male fetus to spontaneously abort. Or, as their last explanation entails, caring for a male child might be more time consuming than caring for a female child – reducing the chance that the parents could engage in a successful copulation for subsequent pregnancies (Blanchard and Bogaert 1997). It is hard to determine, however, if the negative results of shorter spaces between births are because of the spaces themselves or because of extraneous factors such as breast feeding, income, and amount of caregivers.

There have been many recorded benefits the inclusion of breast milk for the first year of life on infant development (Berezkei 2001; Victoria et al. 2016). Breast feeding has also been used as a natural method to regulate the spacing between pregnancies with studies indicating that mothers who breastfeed are half as likely as mothers who do not breast feed to become pregnant after the birth of a child (Victoria et al. 2016). While breast feeding, however, has been found to regulate births, it has also been found that, with increasing births, mothers are less likely to breastfeed their children (Buckles and Kolka 2014). Therefore, not only will the reduction of breast feeding decrease the amount of time between spacing of future children, it can also impair the development of later-born children as they will not receive the necessary nutrients during critical development periods (Berezkei 2001).

For low-income mothers, confounds can be explained by the fact that, on average, low-income mothers have more children than mothers with higher incomes, and there are typically shorter intervals for families with large numbers of children (Feldman et al. 2009). Therefore, some children might have negative outcomes because their families are not able to provide the medical treatment or other services necessary to reduce the negative effects of competition for maternal resources between siblings in early developmental stages. Studies have also found that low-income mothers are more likely than other mothers to be single parents; however, not all mothers rely solely on the father of their child for parenting support – causing differences in birth spacing (Cancian and Reed (2009). Rotering and Bras (2015) found that, for mothers that rely on other family members for child support, spacing between births is increased if the family member is the male grandfather of the child but decreased if the family member is the uncle of the child.

Because of these above mentioned confounds, it is apparent that there are many factors that are responsible for the spacing between births. Regardless, many studies have indicated that small spaces between births can cause increased competition between siblings which, therefore, encourage them to develop different strategies to

obtain the most parental resources which will be discussed in following sections.

Birth Order, Personality, and Parental Investment

Although Sir Francis Galton was the first to hypothesize that first-born's might be more equipped to become scientists because he found that the majority of his peers were first-borns, birth order effects on personality were not truly examined until 1928 with Alfred Adler – the creator of individual psychology. Adler's birth order hypotheses has been found to correspond with the Five Factor Model – also known as the "Big Five" model – of personality which include traits such as: openness to experience, conscientiousness, extraversion, agreeableness, and neuroticism.

Adler broadly states that first-borns tend to be more assertive, quick to please, risk averse, and academically gifted while their younger counterparts are often found to be more agreeable, outgoing, sensation-seeking, and altruistic (Sulloway 1996; Krause et al. 2014). Adler also hypothesized that first-born children typically score higher in neuroticism because their lives are fundamentally changed when a new child is introduced into their family because they are no longer the sole recipient of their parent's affection (Marini and Kurtz 2011).

The results of these initial hypotheses, as well as similar birth order studies conducted by other researchers, are supported by the statements made by Sulloway (1996) who posited that personality differences between siblings might be an evolutionary adaptation – similar to the adaptations of Darwin's finches – used to gain more resources by appealing to their parents in a way that their other sibling or siblings do not. These remarks are founded on the historical basis that, prior to medical advances, parents would have to produce large number of offspring to increase the chances of having a child survive into adulthood to continue their line of genes through reproduction – regardless of their social class (McLanahan 2004). Because the likelihood of surviving to adulthood was not as high as it is in present day, the child's chance of survival was determined almost solely by the amount of resources they were able to procure from their parent (Sulloway 1996).

Sulloway (1996) continues to mention, that although in these families there were numerous children within a family from whom the parents could choose to invest their resources into, parents were most likely to place the most investment into their first-born – especially if they were a male (Healy and Ellis 2007). This emphasis on male heirs, which is still present in many areas of the non-Western world, can be explained by the custom that the eldest males are responsible for “continuing their family name” and were to be responsible for assuming the position of the leader of the family upon the death of their father or other male relative (Sulloway 1996). By having a potential of increased status – and the potential for ownership – eldest males were more likely to find a mate and have higher quality of life than their younger male siblings (Sulloway 1996). Regardless of the sex of the sibling, however, having two or more siblings within a family encourages differentiation of personality, as Sulloway (1996) states, to appeal to one, if not both, parents to receive the resources necessary for survival.

Presently, in Western society, due to the advances in medicine and affordability of healthcare, the odds of losing a child before they reach adulthood have drastically decreased. And, similarly, due to social changes, there is not as much emphasis placed on the offspring needing to be male – unless you are a part of the Royal Family and in search for an heir (McLanahan 2004; Augustine et al. 2015). However, children still remain dependent on their parents for resources which will increase their social, cognitive, and reproductive potential – encouraging siblings to continue developing diverging personalities (Sulloway 1996; Price 2007).

As mentioned above, a first-born’s life is completely changed when a new sibling is introduced into the family because they are no longer the sole recipient of their parent’s resources. Rather, they now must share them with a sibling and will soon find that their parent’s resources are not continuous – encouraging them to develop the particular personalities initially hypothesized by Adler. Sulloway (1996) advances that first-borns are more likely than their later-born siblings to

score higher on measures of conscientiousness and lower on measures of openness to experience (Beck et al. 2006; Krause et al. 2014). These first-born personality traits can be used to encourage a parent to provide resources as scoring high in conscientiousness means that they are more likely to follow parent’s commands – something that many parents yearn to have happen. Similarly, low scores on openness to experience can be seen as a positive adaptive trait as first-borns are more likely to earn their parents favor by being less likely to participate in risky behavior or rebel in teenage and young-adult years.

Conversely, although scoring low in conscientiousness and high in openness to experience could be interpreted as being counterintuitive personality traits that would decrease the amount of parental resources received by later-borns, in some cases, the opposite is true. By being less responsive to parent commands or being more inclined to engage in behavior that could lead to injury or other negative consequence, a later-born child might ultimately receive more parental attention than their rule-following first-born counterparts (Sulloway 1996).

While some sibling personalities might be developed to appease to their parents, some divergent personalities can develop as siblings interact with one another – a key example being that first-borns are arguably more assertive and dominant in comparison to their later-born siblings (Minnett et al. 1983; Sulloway 1996). The development of more assertive or dominant personalities has been attributed to first-borns as they attempt to salvage any control that they had in their lives due to being “dethroned” by the arrival of a younger sibling (Marini and Kurtz 2011). Not only are first-borns more likely to be considered dominant or more assertive when compared to their younger siblings, but due to their age, they are more likely to attempt to “teach” their younger siblings and impose rules (Minnett et al. 1983; Price 2007). Later-born siblings, therefore, have been found to develop personalities that make them traditionally more easy-going, agreeable, and altruistic to deal with the dominating personalities of their first-born siblings. Part of this last statement, however, has been found to be true only for the last-born

child in three child sibships because, in a study conducted by Saroglou and Fiasse (2003), when controlling the study population for nominal birth order, it was determined that last-borns were more likely to display acts of altruism than their first- and middle-born siblings.

While in sibships of two or more siblings are encouraged to develop diverging personalities to gain resources from their parents and to accommodate for the personalities with their siblings, the same cannot be said for only-children who grow up without siblings. Researchers and lay people often believe – and therefore propagate the stereotype – that only children are spoiled because they do not have to compete for parental resources like individuals from sibships (Mottus et al. 2008). Going through childhood without a sibling has also been thought to have negative effects on social or intellectual development – as only-children do not have siblings to help them learn how to navigate the “real world” (see section “[Birth Order, Birth Spacing, Intelligence, and the Only Child Dilemma](#)”; Zajonc and Markus 1975; Price 2007; Mottus et al. 2008).

Though there might be some truth to these beliefs about only children, Mottus and colleagues (2008) believed that these beliefs might be perpetuated stereotypes and might not fully reflect the personalities of only-children. Therefore, they created a study in which they asked young adults to describe the personality of other individuals and themselves based on the Five Factor Model and how many siblings they had (Mottus et al. 2008). Results of this study found that individuals were more likely to view only-children as having negative personality traits (i.e., being more unstable, lonely, etc.) while individuals who came from sibships were rated more positively (i.e., happy, altruistic, etc.) – indicating that individuals do believe stereotypes about only-children (Mottus et al. 2008). However, when discussing the results of the self-descriptive section of the study, Mottus and colleagues (2008) found no significant differences between groups to indicate validity of the stereotypes surrounding only-children. Mottus and colleagues (2008) continue to state that they believe that the negative stereotypes surrounding

only-children orientated in earlier times in which parents were pressed to have multiple children to ensure that there would be at-least one successor that would reach adulthood and successfully reproduce (Mottus et al. 2008).

As hinted at in the paragraphs above, although there have been found to be differences in personality due to birth order, it should be noted that Adler’s research, as well as much of the research conducted after his, on birth order effects on personality only had two categories used to describe individuals – “first-born” and “later-born” (Saroglou and Fiasse 2003; Marini and Kurtz 2011). Because there were only two groups included in these studies, an individual who was labeled as a later-born could be either a second-born, middle-born, or last-born. By not discriminating individuals of higher birth orders into their respective nominal categories, it is difficult to determine if the results reported by Adler are representative of all of the higher-order population or that there was possibly a nominal birth order that was overrepresented among the population – potentially skewing the results. This problem is highlighted by the results of Saroglou and Fiasse (2003) who found that certain personality dimensions, such as rebelliousness, were more descriptive of middle-born children in three children sibships.

Lack of multiple birth-order categories is not the only complaint made by researchers, since Adler’s founding statements, many criticisms have been made about the research design and the potential confounds created by a majority of birth order studies. While there have been many opponents of birth order research which has ascertained connections between birth order and the Five Factor Model, Ernst and Angst (1983) arguably has the most extensive argument as they dissect the results of birth order studies going back 40 years prior (Healey and Ellis 2007). In their review, Ernst and Angst (1983) state that many of the studies conducted after Adler’s 1928 birth order-personality hypotheses did not control for important confounds created by study design, family size, annual family income, and extraneous family factors such as religion (Healey and Ellis 2007).

The first problem with many birth order studies listed by Ernst and Angst (1983) is that, not only do they not differentiate the specific birth orders of later-borns, they also make their assumptions on personality using a between-families method rather than a within-family method. Therefore, results of studies assessing birth order effects on personality are comparing all later-borns against all first-borns as a group, rather than comparing first-borns against later-borns within a family.

Another potential confound in birth order research is that, by not distinguishing the specific birth order position of later-borns, a majority of prior research neglects the overall size of the sibship that an individual comes from. Because of medical advances and the introduction of birth control, many parents are no longer focusing on the quantity of children they produce because, as mentioned previously, the chance of their child dying prior to reaching adulthood has drastically reduced. Now, parents in the middle- and upper-class with higher levels of education are now focusing on the quality of the children they produce. By doing this, these parents are ensuring that all of the children that they give birth to – not just the eldest born male – have the potential to lead productive lives that lead to social, economic, and reproductive success (McLanahan 2004). However, while some parents are reducing the number of children that they produce, lower-class individuals are still producing large numbers of children due to lack of education or availability of various birth control methods (Ernst and Angst 1983; McLanahan 2004). Therefore, a significant difference in personality for higher birth-order children might not be due to their birth order, rather it might be due to the variance in their social-economic status (Ernst and Angst 1983; Beck et al. 2006).

Similarly, critics such as Ernst and Angst (1983) elaborate that children of larger families might also come religious backgrounds, such as Catholicism or Mormonism, that encourage large families – regardless of social-economic status. Not only can religious affiliation have an effect the amount of children in a sibship, it can also effect the development of personality as some religions also place an emphasis on certain

personality traits which they view favorable. These statements are supported by the results Saroglou and Fiasse (2003), which found that individuals who considered themselves to be religious were more likely than their nonreligious counterparts – regardless of birth order – to have higher scores on the conscientiousness and agreeable factors of the Five Factor Model. Analyzing family structure further, Saroglou and Fiasse (2003) went on to find that, in terms of religion, the middle-born is the least inclined to describe themselves as religious and are more likely to have more dynamic personalities because they do not have as many constraints on their personality as first- and last-born children. However, by indicating that there are differences when controlling for nominal birth order, it is clear that birth order has some effect on personality – even if it is hard to discriminate at some points.

Birth Order, Birth Spacing, Intelligence, and the Only-Child Dilemma

As with personality, there are many widely held beliefs on how an individual's birth order affects their intelligence and academic achievement. First-borns have traditionally been believed to be the most likely to succeed academically and have higher intelligence compared to their later-born siblings. Recent theories and models of intelligence, such as the confluence model (Zajonc and Markus 1975) or the resource dilution model, attribute the intellectual success of first-borns to the access of parental resources and the dynamic interaction between other siblings (Downey 2001). However, in regards with only-children, many of these models and theories conflict with resent research that indicate that growing up without siblings can have a detrimental effect on an individual's development of intellectual ability and academic achievement (Price 2007).

The confluence model created by Zajonc and Markus (1975) was designed to explain how the intellectual environment in which a child is raised has a large effect on the future intelligence and later academic achievement. Equations labeled parents as holding the highest intellectual ability by giving them values of "100." Newborn infants were given scores of "0" to indicate that they had

yet to develop any sense of intellectual prowess; however, this score was designed to increase as the child grows older. These scores would be averaged to indicate the level of intelligence of the environment the child is born in by averaging the scores of parents and any child currently present in the family. Therefore, first-borns were born into environments with the highest amount of intellectual potential as each additional sibling would be born into an intellectually inferior environment when compared to the siblings born before them. Zajonc and Markus (1975) also detail that these results are only true when utilizing within-family measures because individual differences between families in regard to family environment reduces the significance in intelligence differences between first-borns and later borns.

Birth order effects on intelligence might be more pronounced in within-family study designs because, when using a between-family study design, birth order effects might be influenced by various social factors such as parental intelligence. Therefore, a later-born from a family with high-intelligence parents might have the same – if not higher – intelligence than a first-born child with parents of low intelligence (Zajonc and Markus 1975). However, being born to lower-intelligence parents might not be the only factor that influences the development of child intelligence because studies have shown that intelligence can be correlated with the availability of parental resources such as attention and money (Zajonc and Markus 1975; Ernst and Angst 1983; Downey 2001).

The resource dilution model is similar to the above-mentioned confluence model because it posits that first-born children will have the highest potential for intellectual ability and that results should only be interpreted within the family because individuals from smaller sibships will obtain more resources than individuals from larger sibships (Downey 2001). This increased intellectual ability for first-borns is believed to occur because, since they will have a time in which they do not have to compete with siblings, they will obtain the most resources over time (Downey 2001).

Aspects of the resource dilution model are supported through the findings of Price (2007) who found that, when comparing the amount of time a parent of two children spends with each child at any particular longitudinal developmental time (i.e., if the children are 2 years apart, measurements would be taken once both children reach 5 years of age, not when one is five and the other is three), both mothers and fathers spend upwards of 25 more minutes with their first-born than their last-born child. Overtime, this difference in parent resource distribution at different developmental stages translates to at least 2000 hours more attention given to the first-born than the second-born. Price (2007) continues on to state that most parents do not know that they are doing this because, by trying to give equal attention to their two kids, they do not realize that they spend more time with one child over another at a certain developmental point. Researchers attempting to find an evolutionary basis for this differential treatment might connect these results with the statements made by Sullo way (1996) that state that even though the families that were alive a century ago had multiple children – parents were more likely to place a greater emphasis on having their first-born survive into adulthood, often neglecting the later-born children. Therefore, first-borns will receive more attention than any later-born child during early developmental stages.

Increased attention can therefore affect intelligence because, when an older child receives more attention than a younger child at early developmental stage, they might receive more assistance than their younger siblings when learning to master specific subjects (Price 2007). Results of Price (2007) are consistent with the resource dilution model because it was found that this effect was likely to perpetuate with the increasing amount of births with the last-born child receiving the least amount of attention during critical developmental times.

Though later-born children might not receive the same amount of parental attention as a first-born child during critical developmental periods, many first-borns or other lower birth order siblings show their mastery of certain subjects by

teaching their younger siblings – potentially making up for the lack of parental attention a later-born child might experience in early childhood (Minnett et al. 1983; Price 2007). This introduction of teaching behaviors in which older siblings are inclined to assist younger siblings might be broadly explained by the evolutionary theory of kin selection because older siblings – especially if they are female – are more likely than their younger siblings to reconstruct concepts that are mastered to their two siblings to whom which the same material is foreign (Pollet and Nettle 2007). And, although teaching behaviors might be a way in which older siblings way of assist or invest their younger siblings, teaching has been found to be more beneficial to the child giving the lesson (Price 2007). This could be because, as mentioned, to teach materials to their younger siblings, older children must find novel ways of explaining material to their younger siblings to help them better understand a concept that they are unfamiliar with – ultimately increasing the older child's mastery of the subject.

The positive effects of teaching behaviors have also been noted by Zajonc and Markus (1975) who state that, while teaching behaviors might increase the intelligence of the a first-born or lower birth order child, these effects are greatly dependent on the birth spacing between siblings. This is because, for the current last-born child in a sibship not having someone with whom they can reinterpret their newly mastered concepts decreases their potential for increased intellectualism; however, if the gap is too large between siblings, the same can be said for children of lower birth order positions (Zajonc and Markus 1975). Zajonc and Markus (1975) continue to state that these negative effects are most prominent in families with multiple children where the spacing between each subsequent child is large. This is because, as mentioned, not having someone with whom a last-born can share their newly learned information with during early developmental stages decreases potential for intellectualism. Therefore, children with larger age gaps in-between them and their youngest sibling will have a lower intelligence because they will

not have someone to share information with during formative, early developmental stages, and, conversely, larger age gaps have been shown to have more benefit the last-born child than short gaps because having older, more mature siblings increases the intellectuality of the family they are born into (Zajonc and Markus 1975). It should be noted, however, that the confluence model is the only model that reviews smaller age gaps as being beneficial. Reviewing the resource dilution model, smaller age gaps have been seen to increase competition between siblings whereas larger age gaps would decrease the amount of differentiation each child needs to gain parental resources to increase their intelligence (Downey 2001).

Regardless of the amount of time elapsed between births, research reports that individuals who do not have younger siblings, such as last-borns and only-born children, are more likely to have deficits in intelligence because they are not given the same experience to teach as children with younger siblings (Zajonc and Markus 1975; Price 2007). However, the notion that an only-child has a decreased amount of intelligence because of their lack of siblings conflicts with both the resource dilution model and confluence model – introducing an issue which could be seen as an only-child dilemma.

This dilemma surrounding only-born children occurs because, after controlling for social confounds, such as income or single parenthood, only-children should have similar outcomes as first-borns when using the resource dilution model or the confluence model because they will be born into a family environment of higher intelligence and will not have to compete for as many parental resources (Zajonc and Markus 1975; Downey 2001). Being an only-born child should also intercede with statements made by both models saying that smaller sibships should have higher levels of intelligence than larger sibships because the only-born is the only child in the family. Because of these potential conflicting results for only-born intelligence, more research should be conducted before any definitive statements are made regarding the effect of being an only-born child on intelligence.

Birth Order and Sexuality

With the increased prevalence of individuals who openly identify as homosexual in Western society, research has been conducted to determine how family factors, such as birth order, might influence the development of homosexuality among males and females. Of the present research conducted on the influence of birth order on sexuality, the maternal immune hypotheses – sometimes known as the fraternal birth order effect – has been argued to be the most probable explanations for the prevalence of homosexuality among males and MF (male-to-female) transsexuals (Gomez-Gil et al. 2011).

The maternal immune hypothesis posits that the likelihood of a male child being homosexual increases with the growing number of older brothers born before him (Blanchard 2001; Gomez-Gil et al. 2011). This would mean, for an example, in a family of all male sons, there is a higher chance that the last-born son will be homosexual than the first-born son – even in two-sibling dyads (Blanchard and Bogaert 1996). Prevalence of male homosexuality occurring in later-borns is believed to be caused in utero as the mothers immune system combats antigens – specifically H-Y antigens – produced by male fetus (Blanchard 2001). This immune reaction increases in intensity with each subsequent male pregnancy because, similar to when your body develops an illness that it had previously recovered from, Blanchard (2001) states that mothers immune systems build in memories in which they are able to detect when a new fetus is male. Blanchard and Bogaert (1997) claim that these immune reactions might therefore cause subsequent male children to have lower levels of various sex hormones than the male children in their biological family born before them. Decreases in these hormones might ultimately be used to explain why, with each sequential male child, the likelihood of them being homosexual increases to where they are 33% more likely to be homosexual than their older brothers born before them (Blanchard and Bogaert 1996; Blanchard 2001). Because homosexuality prevalence has been found to increase with each

additional male birth, homosexual males are more likely to come from large, predominantly male, sibships (Blanchard 2001; Gomez-Gil et al. 2011). However, if a male is from a large sibship, but the majority of his siblings are female, he will not have the same likelihood as being homosexual as the male described in the prior sentence

Similar results were found in a study of MF transsexuals that found that homosexual MF transsexuals (individuals who were born male who transitioned to be female, but are still sexually attracted to men) are more likely than heterosexual MF transsexuals to be a higher birth order child in a family with multiple male children (Gomez-Gil et al. 2011; Hambimana-Kabana et al. 2016). And, in both transsexual and nontranssexual studies, the amount of time between births of males did not influence the prevalence of homosexuality among later-born males (Gomez-Gil et al. 2011; Hambimana-Kabana et al. 2016).

As mentioned previously, however, the maternal immune hypothesis cannot be used to explain the prevalence of homosexuality among women. This is because, according to Blanchard (2001), female fetuses do not produce an H-Y antigen and therefore are not affected by maternal immune response during development.

Birth Order and Mate Selection

As mentioned in the earlier section entitled “[Birth Order, Personality, and Parental Investment](#),” it was discussed that, historically, first-born males have had an advantage when they have reached sexual maturity and are in search of a mate. Sulloway (1996) states that this is because, as the proclaimed benefactor of their parents inheritance and land, first-borns were able to gain the attention of more unmarried women because they were more likely to be able to provide for their future wife and children better than their younger brothers who do not receive an inheritance. By having more potential marriage prospects than their younger siblings, eldest males were not only able to choose a woman who would provide multiple children,

but he could also marry a woman who would make him happy – like many of the men and women in present day.

To explain how birth order might influence the selection of a mate, especially when emotions or personalities are involved, Walter Toman created the duplication hypothesis. According to the duplication hypothesis, an individual is most likely to choose a spouse with whom they can best recreate the birth order in which they resided as a child (Toman 1971). Therefore, if an individual was a first-born in their sibship, they will be more likely to be in a relationship someone who was a later-born in their sibship. However, researchers such as Hartshorne et al. (2009) have found conflicting results indicating that individuals might actually be more likely to choose a mate that shares their birth order.

In his study, Hartshorne and colleagues (2009) found that college students are more likely to form relationships, both romantic and platonic, with people that share their birth order rather than individuals of other birth positions. Hartshorne and colleagues (2009) continue to say that these increased prevalence of same-birth order dyads in relationships might be due to the similar personalities between members of shared birth position – decreasing the validity of the old saying “opposites attract.”

Choosing a mate of the same birth position might ultimately be of evolutionary value because similarities in personality might assist with the successful co-parenting of future children – ensuring they produce socially and cognitively competent children, perpetuating evolutionary value.

Conclusion

Since the founding remarks of Sir Francis Galton in 1874, there have been many hypotheses used to infer information on how birth order effects have evolved over time to effect personality, intelligence, sexuality, and mate selection. Many of these initial hypotheses indicate that within a family, the first-born is traditionally at an advantage in comparison to his siblings.

Today, this is believed to be because he is able to attain more resources and is born into an environment of higher intellectuality, while in years past, it was because he would be the beneficiary of the family inheritance and therefore was provided more resources to survive into adulthood.

Other hypotheses created indicate that, for males, birth order might play a large role in determining their sexual preferences with later-born males being more likely to be homosexual if in a multiple-male child sibship. While some of these recent studies have focused on sexuality, other studies have reviewed the effect of birth order on mate preference – leading to two conflicting hypotheses either agreeing or disagreeing with the age old saying “opposites attract.”

By living in an ever-changing society, family dynamics are also changing. While these hypotheses can be used to partially explain differences between birth orders, because of changing dynamics, more research should be conducted before definitive statements are made.

Definition

Childbirth is a complicated process for humans that is often accompanied by anxiety and discomfort, which can be relieved with emotional support.

Introduction

Giving birth seems to be more complicated and challenging for women than it is for females of most other mammalian species. A number of explanations for birthing complications have been offered including the large size of the human neonate, the anatomical limitations of the bipedal pelvis, unwarranted medical interventions in what is usually a straightforward process, and complex psychological and emotional reactions to labor and delivery.

Human Birth

Most human births occur vaginally with the infant in the vertex (head down) position and without problems, but complications occasionally arise, some of which benefit from consideration within the context of human evolutionary history and, especially, evolutionary psychology. Example birthing complications that can be considered in an evolutionary context include prolonged labor, abnormal or unusual presentation of the fetus (e.g., breech), cephalopelvic disproportion, and

both medical and elective cesarean section. Additionally, many unproblematic deliveries may be designated as complicated based on highly subjective definitions and varying hospital practices (Cunningham et al. 2014).

Anatomical Factors and Birthing Complications

As a result of our evolutionary history, humans have large babies and complex birth canals, leading to challenging births. Humans are not unique in having difficult births, however – monkey infants are also large relative to their mothers' bodies, and births in captive primates sometimes present difficulties that can result in infant death without assistance from veterinary staff. Complications that have been reported for monkeys include breech deliveries, dystocia, and cephalopelvic disproportion but at far lower rates than reported for humans (Schlabritz-Loutsevitch, et al. 2018). What is unusual about human birth is the series of rotations the infant undergoes as it navigates through the tight dimensions of a pelvis that has evolved for bipedal walking rather than for easy birth. Furthermore, human births typically occur with some form of social support and assistance, a phenomenon that has been reported for other primates but is far from routine and expected (Trevathan 2015).

Unlike the quadrupedal pelvises of monkeys and apes in which the birth canal is a relatively straight passageway from inlet to outlet, the human adaptation to bipedalism has resulted in a birth canal that is twisted in the middle. Additionally, the way in which the infant begins its emergence from the birth canal is different for humans and nonhuman primates. Most monkeys are born with the head extended in a face presentation (Trevathan 2015; Schlabritz-Loutsevitch et al. 2018), a type of delivery that would be considered an obstetric complication in humans. The monkey infant typically continues to emerge facing the same direction as the mother ("occiput posterior"), whereas the typical human presentation is "occiput anterior" with the back of the infant's head against the front of the mother's pelvis so that it emerges facing away from the mother. This emergence pattern has been suggested to account for the selective

value of having assistance at birth for guiding the infant from the birth canal (Rosenberg and Trevathan 2018). Giving birth in the presence of another person who can wipe the fluids from the newborn infant's face, unwrap the umbilical cord from around the neck if it is too tight, and guide the infant toward the mother's breast may avoid complications that are often associated with childbirth. Helping the infant make contact with the breast may play a role in inhibiting postpartum hemorrhage, one of the most common causes of maternal death related to childbirth (<http://www.who.int/mediacentre/factsheets/fs348/en/>). Human mothers can do this alone, but maternal and infant mortality and morbidity have probably been reduced throughout history when assistance is provided.

What Role Do Psychological and Emotional Factors Play in Making Birth Complicated for Humans?

The ultimate explanation for assistance may be lowered mortality (and greater reproductive success for those who have assistance), but the proximate explanation is more likely that the laboring female seeks emotional support at a time when she feels vulnerable and anxious. Humans are notably socially gregarious mammals, and seeking companionship during times of heightened emotions is normal and expected. Giving birth is probably one of the most emotionally and physically challenging life events that a woman experiences (Simkin 1996). Women who report feeling anxious and fearful about the pain of childbirth are often advised to be treated with pharmaceutical and other medical interventions up to and including elective cesarean section. Randolph Nesse (1991) has argued that a number of psychological problems can better be understood as *defenses* that have been naturally selected because of their benefits to survival and reproductive success. Examples are phobias that may lead a person to avoid potential dangers such as snakes, rocky ledges, and jumping out of airplanes. Sadness in response to a failed love relationship, flunking a test, or being fired can provide time to reflect on causes and to develop strategies for improving outcomes in subsequent ventures. Following this logic, anxiety during

labor and delivery can lead the typically gregarious human female to seek companionship and social support when she is preparing to give birth. Anxiety can also help a woman to focus cognitively, emotionally, and physically on the task of delivering an infant. In all of these examples, the phobia, sadness, or anxiety can become extreme, leading to a variety of undesirable outcomes that have negative fitness consequences, at which point they become, in Nesse's words, "defects" that may require medical or psychological interventions.

What Role Do Modern Medical Interventions Play in Making Birth Complicated for Humans?

Although it is clear that there are complications associated with childbirth that cannot be resolved without medical intervention, many would argue that there are perhaps more cases in which intervention *causes* complications. At the very least, there is increasing evidence that obstetric interventions add to the financial costs of childbirth and reduce maternal satisfaction with their birth experiences without adding any benefits for women at low risk for complications (Tracy and Tracy 2003; Tracy et al. 2007). Furthermore, interventions at one birth often lead to intervention in subsequent deliveries.

The ultimate intervention when birthing complications become life threatening is surgical delivery of the fetus, or cesarean section. The most common medical reasons for cesarean section in the United States are labor arrest (34%), problems with fetal heart rate (23%), fetal malposition (17%), multiple gestation (7%), and suspected fetal macrosomia (4%) (Barber et al. 2011). Many of these "causes" relate to expectations that are culturally constructed and that may not be considered as legitimate reasons for cesarean section in some contexts (Rosenberg and Trevathan 2018). For example, labor arrest is based on highly variable definitions of what length of time in labor becomes excessive, leading to surgical delivery (Zhang et al. 2010). In other words, although long labors often lead to healthy neonatal outcomes, if attendants perceive labor length as excessive, they often offer

cesarean section. Without support for alternative options, an exhausted mother in labor may quickly accept this suggestion and deliver her infant surgically.

Conclusion

In conclusion, birthing complications may require technological interventions up to and including cesarean section, but increasing awareness of the range of healthy variability in physical and emotional aspects of birth will likely improve outcomes for women and infants all over the world. Understanding the evolutionary context of the physical challenges of giving birth and the powerful emotions surrounding this event will likely lead to improved environments of birth, reductions in the well-known high rates of cesarean section, and improved emotional health following what is likely one of the most significant experiences of a woman's life.

Definition

The way ancestry influences social behaviors and interactions.

Introduction

Humans receive three crucial things from their ancestors: their genes, their kin, and their

traditions (Lyle Steadman, 1981, personal communication). Like all forms of life, humans are tremendously influenced by the genes they inherit from their ancestors. Starting at conception, these genes interact with countless aspects of the environment, in complex ways that are just beginning to be understood, to form the physiological and behavioral phenotype of the individual. Like many species, a key aspect of the environmental factors influencing a human's development is the closely related kin, both living ancestors (e.g., parents and grandparents) and co-descendants of those ancestors (e.g., aunts, uncles, nieces, nephews, and first cousins), that the developing individual interacts with throughout their lifetime. However, although many species copy the behavior of parents (Avital and Jablonka 2000), humans are unique in the extent to which their development and evolutionary success are influenced by traditions: the behaviors that have been passed down from one generation of their ancestors to the next, sometimes for hundreds of generations, before being copied by the developing human. Some of the traditions passed down through specific sequences of ancestors and descendants (i.e., bloodlines) drawing the most attention from evolutionary psychologists have been those leading to the intergenerational transmission (i.e., inheritance) of various forms of wealth and status (i.e., birthrights).

The Generational Depth of Bloodlines and the Breadth of Co-descendants

The evolutionary study of birthrights and bloodlines can be conceptually organized on the basis of the generational depth of the bloodlines in question, which in turn determines the breadth of currently living co-descendants being studied. Studies on differences in how parents treat offspring (Borgerhoff Mulder 2000), including the differential transmission of wealth and status to those offspring, involve differences between siblings. This research often uses the evolutionary concept of parental investment theory to study differences based on the sex of the offspring, and the concept of parent-offspring conflict to study

other differences such as birth order (Draper and Hames 2000). Such studies have been performed on populations at various levels of social complexity, and tend to focus on how sex and birth order influence the inheritance of wealth, property, and status, and how these differences in inheritance influence, in turn, the inclusive fitness of the individual siblings. Perhaps the most well-known influence of birth order is primogeniture, where the first born son inherits most of all of the wealth, property (e.g., land, house), and/or status (Low 1990).

Sometimes studies on intrafamily differences in parental treatment of offspring focus on the relative status of the family within the larger social environment. One type of this category of studies examines how the sex of the offspring influences their inheritance and treatment by parents in relation to the family's relative socioeconomic status. These studies often examine the hypothesis that sons will receive better parental treatment and inherit more in higher socioeconomic classes (Dickemann 1979), while the same will be true of daughters in lower socioeconomic classes (Cronk 1989). This hypothesis is based on the fact that whenever formal or de facto polygyny occurs, the highest quality males will have greater reproductive success than the highest quality females, but the lowest quality females will have greater reproductive success than the lowest quality males. Primogeniture within a family can also be studied within the larger context of interfamilial differences in wealth, power, and status (e.g., European monarchies).

Studies focusing primarily or exclusively on differences between families focus on the consequences of differences in behaviors, wealth, and status transmitted through longer lasting multi-generational bloodlines to form lineages, clans, and ethnic categories. These studies sometimes focus on the inheritance of certain positions of status such as headman and shaman among foragers and other highly traditional cultures. However, most of this research focuses on inequalities which have become more extreme as social complexity and social stratification has increased. These range from royal lineages to the development of caste systems but have in common a

focus on the long-term inheritance of wealth, power, and status in certain lineages (Shenk et al. 2010).

Conclusion

While these studies of bloodlines and birthrights have been very productive, perhaps the most fundamental and important influences of traditions have been largely overlooked by evolutionary researchers. This is the influence of traditions on behavior toward co-descendants of a common ancestor. This influence not only includes identifying these individuals as kin but influencing these individuals to behave in certain altruistic ways toward these individuals (Palmer et al. 2016), a form of behavior characterized as the axiom of kinship amity (Fortes 1969). This is a puzzle to orthodox evolutionary theory because this amity extends far beyond the range of kin selection and produces altruism failing to conform to predictions generated by reciprocal altruism and multilevel (i.e., group) selection. The consequences of such traditions include the ubiquitous segmentary nature of bloodlines, which tends to characterize human social organization (Coe et al. 2010). Thus, incorporating traditions into evolutionary explanations of human behavior is a major challenge.

Definitions

Taken to its literal extreme, a *blank slate* view of human nature is “the idea that the human mind has no inherent structure and can be inscribed at will by society or ourselves” (Pinker 2002, p. 2); “The belief that humans are very malleable and that most group and sex differences are caused by variation in the environment, not by differences in genes” (Winegard 2018).

An *implicit* or *quasi-Blank Slate* (i.e., *Blank-slate-like*) theory of human nature involves believing that biology is important, in some way, for

explaining human minds and behavior, but often maintaining the idea that nature and nurture are disjoined and/or opposing causes (rather than integrated), with environments (particularly socially constructed knowledge) being considered the predominant causes of many/most aspects of human personality, cognition, and social behavior, independent of consideration of evolutionary/genetic/biological causes.

Introduction

In *The Blank Slate: The Modern Denial of Human Nature* (2002/2016), Steven Pinker describes how and why many modern academics and intellectuals reject (sometimes vehemently) a biologically based conception of human nature in favor of an epistemological view (known as a *Tabula rasa* or Blank Slate view) that all human knowledge comes from perceptual and experiential learning. Modern academics and intellectuals appear to accept and defend the latter view based, at least partially, on fear of four perceived implications of a biopsychological conception of human nature: (1) fear of inequality, (2) fear of imperfectability, (3) fear of determinism, and (4) and fear of nihilism. He argues the feared perceived implications from acknowledging an evolved human nature are nonsequiturs. In addition, Pinker (2002/2016) argues blank slate views are often associated with (1) a belief in the “noble savage” myth that people are inherently morally pure and corrupted only by “bad” societal influences and (2) a belief in the “ghost in the machine”; the assumption that human choices are free from biology. These auxiliary beliefs support and protect the Blank Slate view by “explaining” bad behavior independently of biology or any evolved human nature. Pinker’s book documents the great lengths that intellectuals have gone to deny influences of human nature and to promote a Blank Slate-like view within academia and the larger culture. He defends the idea of an evolved (and sex-differentiated) human nature with empirical evidence and responds to common moral and political criticisms of an integrated-evolutionary view of human nature.

This entry describes why a *literal* blank slate view is intellectually incoherent and implicit or quasi-blank slate views are also scientifically indefensible, but common. It describes ways blank slate perspectives conflict with biologically unified perspectives on how, mechanistically, “nature” (i.e., evolved organization through genetic/epigenetic influence) interacts with experiential learning. It contrasts blank-slate-like interpretations of recent findings of environmentally induced epigenetic changes with an evolutionary-selectionist interpretation of such findings and argues that recent epigenetic research is more naturally supportive of selectionist accounts of development which suggest evolution has shaped epigenetic mechanisms that include both genes and the “built-in” developmentally relevant “environments.” Finally, it argues that blank slate beliefs are deeply entwined with, and partly motivated by, ideologically based concerns driving a rejection of the notion of evolved psychological and sociological characteristics (Horowitz et al. 2014; Von Hippel and Buss 2017; Winegard 2018; Van den Berghe 1990), leading to an untenable, intellectually bankrupt view of human psychology and societies (Van den Berghe 1990).

Human Nature and the Role of the Environment: Instruction Versus Selection?

Taken to its literal extreme, the Blank Slate (BS) view is the (scientifically incoherent) “belief that humans do not have a “nature” and are entirely molded by environmental/cultural forces” (Winegard 2018). This view implies that, prior to experiential learning, there is no substantial evolved organization to (or biological constraints on) human psychology, experiential learning mechanisms, or behavior. It also implies there are no “innately” structured psychological differences between the sexes.

BS views also assume that pure *instruction* (e.g., by meaningful “information”) from the environment and culture dominate brain, mind, and behavioral development (Gazzaniga 1992). In other words, BS views assume the role of

experience in the development and functioning of higher brain functions is to freely *instruct* or “teach” neuro-cognitive internal machinery about how to do, operate, organize, construct, or assemble something new; it assumes few built-in governing and enabling constraints on how social and cultural environments infuse novel “content” (e.g., new associations) into the human brain’s machinery, reshaping human psychology as if brain’s were “silly putty” (Pinker 2002) being shaped by a culture, supposedly separate from evolutionary-genetic influence. Because a *literal* (incoherent) blank slate has *no* innate “if-then rules” for how to respond adaptively to ecological contexts in particular ways (i.e., epigenetic rules, describable by reaction norms), an organism could not respond in *any* predictable way (or at all) to environmental stimuli presented by its particular socio-ecological context, let alone with species-specific adaptive behavior. Thus, a *literal* blank slate, is scientifically incoherent and untenable (Tooby and Cosmides 1992).

Possibly because a *literal* blank slate is obviously nonsensical, many social scientists and others adopt *implicit* or *quasi*-blank slate (blank-slate-like) assumptions about the power of socialization (e.g., influences of parenting, media, the presentation of “information,” raising awareness through education, gender roles, “rape culture,” patriarchy, toxic masculinity, etc.) and use those assumptions to ground the belief that properly structured experience can completely “overcome” any biological influences of human nature and effectively re-engineer the human mind and human society, at will, according to current cultural, political, or moral preferences.

To make any sense, however, a quasi-blank slate set of assumptions requires that many “if-then rules” guiding how to respond to a given ecological situation are, themselves, created through experience, “without any reference to biologically adaptive outcomes” (Wilson 2007) or that there are only a few, relatively general, such innate rules that govern how experiential learning “forms” human psychology/knowledge. Using information-processing terminology to describe such “If-then rules,” Tooby and Cosmides (2016, p. 34) write,

Even if a program that causes a particular kind of learning was itself learned, there had to be a prior program that caused the learning to occur, and so on. Logic forces us to conclude that there had to be, at some point in the developmental causal chain, a program that caused learning but that was itself unlearned.

In other words, ultimately, the “rules” that we create to describe how individuals are affected, developmentally, by environmental stimuli and how individuals learn from environmental experience must be innate. Therefore, coherent “environmentalists” and “nativists” must agree there are innate “rules” or regularities for how experience changes psychology and behavior, but disagree about the form, content, specificity, and number of those “rules” (or “programs”) (Tooby and Cosmides 2016).

An extreme implicit BS thinker might confidently claim pure environmental causation by stating that “Society *dictates* that boys/men should act one (“toxic”) way to be masculine and girls/women should act another to be feminine” and predict that changing such “societal messages” about gender-related behavior and preferences will solve a number a societal problems/behaviors. Such claims are, however, made without considering at least three biologically viable possibilities: (1) innate differences between biological males and females that contribute to average differences in their psychological/behavioral characteristics, (2) biological differences that contribute to the sex-differentiated characteristics of the society itself (because “societies” aren’t mysteriously uncaused or disconnected from individual brains), and (3) biological differences that contribute to cross-culture/society (and cross-species) consistency seen in the same pattern of sex difference characteristics. In other words, these claims are “just-so stories” about pure socio-cultural causation and they are contradicted by substantial evidence of consistent biological sex differences across species (e.g., Janicke et al. 2016) and across human cultures.

In contrast to BS-like thinking, evolutionary and biopsychological perspectives in the behavioral sciences suggest there is a biologically prepared human nature that has been substantially shaped by various forms of selection and that this evolutionarily shaped

organization is itself what, adaptively, both *enables and constrains* different social and ecological conditions to elicit the many varieties of human behaviors that occur (Lumsden and Wilson 1980, 1981; Tooby and Cosmides 1992). Some evolutionary perspectives suggest that, during proximate-developmental time, specific environmental features *select* from (or “trigger”) the evolutionarily prepared “contents” of human nature. The most extreme form of a (proximate-level) *selectionist* theory “is that an organism comes delivered to this world with all the world’s complexity already built-in” and “the environment selects from the built-in options” rather than modifying them (Gazzaniga 1992; see also Edelman 1987).

Evolutionary perspectives invite us to ask *why* a particular kind of experience has the particular effect it does, rather than *whether or how much* of something is due to environmental experience (Gaulin and McBurney 2004). In other words, in many respects, a satisfactory explanation of why experience (including aspects of cultural experience) affects individuals in particular ways *requires* an evolutionary perspective. These ultimate-level “why” questions also guide us toward asking better proximate-developmental and mechanistic questions. Thus, both BS theorists and evolutionary perspectives propose the environment is developmentally (and theoretically) crucial, but many evolutionary thinkers argue BS-like theorists (often) misunderstand a sensible way to conceptualize the *role* of the environment and *how* experience interacts with biological machinery (note: there is also variety in how evolutionary theorists conceptualize the role of the environment; see Gladden & Jacobs, ► [“Information Processing and the Interdisciplinary Perspective”](#) entry, this volume).

Experiences do not capriciously change our psychology or behavior. As Gaulin and McBurney 2004, p. 10) put it, in information-processing talk, “Evolution has preprogrammed an interaction between genes and environment.” Since evolutionary selection is fundamentally about organisms being shaped by the consequences of environmental change, only by the oddest of assumptions could anyone expect an evolutionary perspective to deny the capacity for

change in response to environmental features (Wilson 2007). It should be an obvious prediction of evolutionary theory that selection crafts proximate mechanisms *enabling (and constraining)* organisms to respond adaptively to, recurrently, important environmental stimuli (e.g., unlearned reinforces and punishers). But BS-like assumptions and an *unconstrained* vision of human nature can promote misunderstanding about *how* experience has its effects and *how* experience/context interacts with biological machinery to guide behavior.

Fear of Genetic Determinism, the False Nature-Nurture Dichotomy, and (Intraindividual) Gene-Environment Interactions

Most Psychologists seemingly agree that many, most, or even all behavioral traits are “due to both nature and nurture.” And most will repeat that behavioral traits result from an “interaction” between genes and environment. So, superficially, BS-thinking doesn’t appear to be a widespread problem in Psychology. But when asked to explain, *mechanistically*, how experience shapes a *single individual’s* traits and *how* genes and environment “interact,” disagreement becomes obvious. For example, many persist in talking about genes and environment as entirely separate influences on individuals that each *independently* affect a trait. These separate influences, the thinking goes, have *additive* effects on the individual’s trait, with some traits seen as more “inherited” or “innate” and others as more due to the environment. This (misguided) way of thinking allows for implicit BS thinking to flourish because, if we can control the “environmental” portion of the trait, a person with such dichotomous nature versus nurture thinking believes it “overrides” the nature portion. This way of thinking is *mechanistically* incoherent because it incorrectly assumes that nature and nurture are opposed forces, inexplicably working *competitively* against each other. Similarly, it’s inconsistent with a true *mechanistic interaction* where the activity of particular genes (and other inherited factors) depend on (i.e., are

“switched on or off” by) particular evolutionarily important social and ecological conditions, and the effects of particular environments depend on particular genes. It’s important to point out that the term “interaction” is more commonly used as a *statistical* term to account for behavioral *differences* across individuals in a sample rather than a *mechanistic* one (as used above) to describe actual causes at the *intraindividual* gene-experience interactions. These two levels of understanding cannot be carelessly conflated.

A second misguided, B.S.-like way of thinking about how experience and genes “interact” is to think that individuals inherit a broad “range” (or “potential”) for traits and experience/environments determine where, within that range, an individual ends up. But while this might be a useful way to describe, for novice undergraduates, how to think about how genes and environment “work together,” genes don’t literally prescribe or transmit any “range” per se. More importantly, Gaulin and McBurney 2004, p. 9) point out that this way of thinking doesn’t go far enough to describing *how* (mechanistically) experience shapes traits:

Many social scientists make the following kind of argument: Nature (or the genes) sets the limits, but experience shapes the trait within these boundaries. This is the familiar claim that our genes have us on a long leash, and it is a second naïve meaning of the claim that x is due to both nature and nurture. It is just as erroneous as the percentage approach. The problem with this way of thinking is that it fails to address the very large problem of exactly how experience shapes the trait. How can it shape the trait except by rules of gene-environment interaction that are coded in the genes? Could UV_B exposure raise IQ? Yes, if there were genes encoding such mechanisms, and no if there were not. To say that experience shapes the trait with broad boundaries amounts to sweeping most of the interesting questions under the rug. . .

The “nature as setting a broad potential” idea might be descriptively true (as far as it goes), in a (superficial) sense. But this way of thinking enables/encourages dichotomous, non-mechanistic, and noninteractive (i.e., implicit B.S.) beliefs to proliferate. These ways of thinking about nature and nurture allow many people to believe in a mind/brain with blank slate-like properties without believing they believe in a blank

slate because they are able to acknowledge that genetic effects are important for *something* (determining a nebulous broad “range” or “limit” or “potential”), but still end up treating nurture as the *predominant* determining force to shape us like “silly putty” within an extremely broad range or limits (without clearly defining what those are). The “nature as setting a broad potential” view is blank slate-like because it doesn’t go far enough in explaining *how* (mechanistically) experience shapes the trait.

These ways of thinking are inconsistent with much evolutionary thought about what genes evolved to do. Genes respond to particular features of the environment in a particular way that is *organized by innate* “if-then rules,” shaped by evolution. Pitting them against each other or treating them as entirely different types of opposing forces isn’t mechanistically sensible. And, as Pinker (1997/2009, p. 33) points out, “having a lot of built-in machinery should make a system respond *more* intelligently and flexibly to its inputs, not less.” So, while an innate organization does, of course, place guiding constraints and structure on the kinds of effects environments will have (i.e., it won’t work anything like silly putty), an understanding of the evolved structure of the mind is not just consistent with, but often *necessary* to effectively identify factors that could minimize social problems. Studying human nature with an evolutionary perspective encourages attempts to understand the particular evolved “if-then rules” or regularities by which environments have their effects.

Tooby and Cosmides (1992) pointed out well that the (developmentally relevant) *environment evolves*. Many genes evolve to be triggered by particular events experienced by the organism and, thus, in some nonliteral “if-then rule” sense, the “environment” is “innate”:

The assumption that only the genes evolved reflects a widespread misconception about the way natural selection acts. Genes are the so-called units of selection, which are inherited, selected, or eliminated, and so they are indeed something that evolves. But every time one gene is selected over another, one design for a developmental program is selected over another as well; by virtue of its structure, this developmental program interacts with some aspects of the environment rather than others, rendering certain

environmental features causally relevant to development. So, step by step, as natural selection constructs the species’ gene set (chosen from the available mutations), it constructs in tandem the species’ developmentally relevant environment (selected from the set of all properties of the world). Thus, both the genes and the developmentally relevant environment are the product of evolution

From their perspective, human nature (the evolved structure of the human brain/mind) *is* a set of reliably-developing, complicated, computer-like *programs* (complex sets of instructions/algorithms) that determine how environments affect behavior. Natural selection, they say, sculpts these “programs” by operating on a “systematically caused *relationship* between information and behavior” (Tooby and Cosmides 2016; but see Gladden and Jacobs 2019, this volume). In other words, these Darwinian “programs” are what Lumsden and Wilson (1980, 1981) termed *epigenetic rules*. With respect to gene-culture coevolution theory, Wilson (1998) described how innate epigenetic rules select/guide how features of the local culture affect psychological development:

Genes prescribe epigenetic rules, which are the neural pathways and regularities in cognitive development by which the individual mind assembles itself. The mind grows from birth to death by absorbing parts of the existing culture available to it, with selections guided through epigenetic rules inherited by the individual brain. (p. 138).

Natural selection operates on variation in epigenetic rules, not genes acting alone or independently of environmental interactants. This means that understanding why environments have particular developmental effects often can’t be understood without understanding evolved epigenetic rules (i.e., biological human nature).

BS Assumptions and Confirmation Bias Mislead Interpretation of Epigenetic Studies of Experience-Induced Gene Regulation Changes

In a recent variant of BS-like thinking, many social scientists with implicit-BS assumptions believe results from epigenetic studies of experience-

induced, gene expression changes confirm their belief that “environments” rather than “genes” control the associated behavioral changes by *instructing*, *directing*, or causally *leading* the genes to make changes involved in behavioral outcomes. Or such findings about DNA methylation are believed (by implicit BS theorists) to (1) “give us license to...embrace a holistic interactionism” without careful/proper causal analysis of its component interacting parts (Pinker 2016, p. 434) and/or to (2) radically alter our understanding of genes and development (e.g., González-Pardo and Álvarez 2013). But a *concept* of epigenetic changes during development, activated by the environment and interacting with genotypes is older (e.g., Waddington 1942) than Watson and Crick’s (1953) publication of the physical structure of DNA. So, these new discoveries about the actual physical mechanisms of genetic *activity* are exciting and enlightening, but not *conceptually* new or revolutionary. Indeed, epigenetic rules of human social behavior were the central feature of Lumsden and Wilson’s (1981) theory of gene-culture coevolution, which suggests a strong nativist/selectionist view of cultural learning that “genes hold culture on a leash” because genes prescribe innate epigenetic rules of culture (though the “leash” is flexible). Thus, new mechanistic discoveries supporting the concept of experience-induced epigenetic changes does not imply that environments are suddenly more important than previously thought or “taking the lead” over DNA in controlling phenotypes. Such epigenetic discoveries were, apparently, expected/predicted by sociobiologists decades before most social scientists had ever heard of epigenetics. Further, it is an error to think that “genetic” and “epigenetic” effects or developmental processes are inherently different things because DNA doesn’t work by magic or somehow autonomously, disconnected from any external regulation. Thus, “genetic” effects are always “epigenetic” (in a developmental process rather than inheritance sense) because a gene is, presumably always, regulated by something other than its own *volition*. These basic epigenetic findings don’t suggest anything about the

“relative importance” of environments versus genes in controlling/leading the development of phenotypes or anything specific about the degree of canalization of the trait. Since evolutionary selection is obviously expected to craft innate mechanisms enabling organisms to respond adaptively to (recurrently) important environmental stimuli (as described above), only by the oddest of assumptions should anyone expect experience to be unable to change gene expression in an *adaptively constrained* way (Pinker 2016). But this doesn’t free the environment to alter human nature (or epigenetic rules).

A proximate-level selectionist interpretation (as described above) of studies examining experience-induced epigenetic changes in gene expression proposes that evolution organizes a diverse neural, psychological, and behavioral repertoire *in advance* and that environmental features “select from” or trigger these evolutionarily prepared sets of neural and phenotypic options. Thus, organisms come to produce behavior that solves environmental adaptive problems effectively, not because the environment *instructs* the genes how to do something new, but because evolution has shaped epigenetic mechanisms that behave *as if* they include both genes *and* the “built-in,” developmentally relevant “environmental cues” or triggers. From this view, the environmental features associated with specific classes of adaptive problems developmentally trigger innately organized and environmentally contingent “options” and such environmentally activated epigenetic effects are themselves under the constrained control of DNA, along with inherited transcription factors (e.g., gene “switches”). Furthermore, Chernyavskaya et al. (2017) point to evidence that “DNA methylation does not serve as a universal mechanism of repressing gene expression” and “although DNA methylation contributes to the regulation of some genes, many studies have led to the conclusion that this function is the exception rather than the rule.” In other words, DNA methylation changes are not always, themselves, causal of gene expression changes. Further, Hannon et al. (2018) found that variation in DNA methylation at sites associated with environmental variables is also partly heritable, possibly suggesting control

by genes as to whether and how much particular environmental factors affect DNA methylation.

Unconstrained Visions of Human Nature and Leftist Political Homogeneity among Social Scientists

Pinker (2002), citing Thomas Sowell's *A Conflict of Visions*, argues that blank slate-like beliefs, including a belief in human perfectibility are based in an *unconstrained* (or *utopian*) vision of human nature and are, generally, (though not always) associated with leftist political beliefs. In contrast, evolutionary psychological perspectives suggest a *constrained* (or *tragic*) vision by acknowledging enduring characteristics of human nature and acknowledging individual biological variation. Arnhart (2005) notes:

those with the realist" (constrained) "vision of life believe that since the moral and intellectual limits of human beings are rooted in an unchanging human nature, a good social order must make the best of these natural limitations rather than trying to change them. But those with a utopian vision of life believe that since the moral and intellectual limits of human beings are rooted in social customs and institutions that are changeable, the best social order would arise from rationally planned reforms in these customs and institutions that would perfect human nature. (p. 6)

In the *Utopian/unconstrained* vision, human nature changes with social circumstances and by tinkering with those social circumstances we will re-fashion human nature. In the *Tragic/constrained* vision, social circumstances/traditions are "...spontaneously evolved rather than rationally designed" (Arnhart 2005, p. 7) and "let us work around the shortcomings of human nature" (Pinker 2002, p. 288). Pinker (2002) agrees that "the new sciences of human nature really do vindicate some version of the Tragic Vision and undermine the Utopian outlook" (p. 293) and advocates for thinkers on both the political right and left to modify their political alignments as we learn more about human nature.

Consistent with the idea that deeply entrenched ideological convictions drive beliefs in an unconstrained human nature and an implicit blank-slate, Buss and Von Hippel (2018) (see

also Von Hippel and Buss 2017) reported the results of a survey of 335 Social Psychologists, finding that, although Social Psychologists overwhelmingly report they believe in evolutionary theory and that it generally applies to humans, they are much more split about whether evolution has shaped many social attitudes and preferences (with a significant minority evidently rejecting the idea) and divided about whether some specific findings/conclusions that contradict blank slate-like beliefs are likely to be true. They found some preliminary evidence that far left political ideology correlates slightly with at least some blank slate-like beliefs (e.g., rejection of the possibility that "sex-differentiated hormones such as testosterone and estrogen have a major influence on our attitudes and behavior"). One limitation of these findings is that there are almost no politically conservative social psychologists, so the sample is overwhelmingly politically homogeneous like the field has become since the 1990s.

Duarte et al. (2015) advocated for increased political diversity in social psychological science to reduce ideological and confirmation biases, particularly because the field deals with ideologically controversial topics that human reasoners are hopelessly biased about. When there are too few conservative perspectives on ideologically charged topics (i.e., lack of viewpoint diversity), there is insufficient collective scientific correction. As Haidt (2013) notes, just as the political right is full of young-earth evolution deniers and climate change deniers, the political left is full of IQ-deniers, heritability deniers, biological sex difference deniers, evolutionary psychological science deniers, and stereotype accuracy deniers. Each of the latter "science-denial groups" involves blank slate-like thinking. Thus, if BS-like thinking on "hot-button" topic becomes sufficiently orthodox, it can slow or even halt scientific progress in those areas.

The situation for human nature denial in Sociology is even worse. In a sample of 155 Sociological theorists, Horowitz et al. (2014) found:

Just over half the theorists in our sample deny the role of natural selection in shaping a range of human tendencies. Many more are unwilling to acknowledge the plausibility of evolutionary arguments applied to sex differences.

Much Sociological theory treats “culture” or “society” as an uncaused (autonomous) cause, separate from individual biological brains, and not connected to psychological explanations involving evolution or genes (Van den Berghe 1990). A common charge is that evolutionary or “genetic” explanations of societal phenomena are “reductionist.” Dawkins (1996) defends hierarchical (intertheoretic) “reductionism” as a fundamental scientific tenet for trying to make sense of things:

“To call oneself a reductionist will sound, in some circles, a bit like admitting to eating babies. But, just as nobody actually eats babies, so nobody is really a reductionist in any sense worth being against. The nonexistent reductionist – the sort that everybody is against, but who exists only in their imaginations – tries to explain complicated things directly in terms of the smallest parts, even, in some extreme versions of the myth, as the sum of the parts! The hierarchical reductionist, on the other hand, explains a complex entity at any particular level in the hierarchy of organization, in terms of entities only one level down the hierarchy; entities which, themselves, are likely to be complex enough to need further reducing to their own component parts; and so on. It goes without saying though the mystical, baby-eating reductionist is reputed to deny this – that the kinds of explanations, which are suitable at high levels in the hierarchy are quite different from the kinds of explanations which are suitable at lower levels. This was the point of explaining cars in terms of carburettors rather than quirks. But the hierarchical reductionist believes that carburettors are explained in terms of smaller units. . . , which are explained in terms of smaller units. . . , which are ultimately explained in terms of the smallest fundamental particles. Reductionism, in this sense, is just another name for an honest desire to understand how things work.” (Richard Dawkins 1996, p. 13)

Conclusion

Many behavioral scientists with blank slate-like beliefs hold misconceptions about evolutionary psychological perspectives (e.g., Von Hippel and Buss 2017), including believing that evolutionary psychology advocates “genetic determinism” rather than an integrated interactionist perspective. Implicit blank slate views are entangled with unconstrained visions of human nature, the naturalistic fallacy, and sacred liberal values

concerning fairness/equality and social justice. When, due to a lack of political viewpoint diversity, sacred beliefs/values are overwhelmingly agreed upon (and “socially enforced”) within social science fields when truth and sacredness do inevitably come into conflict, there is a lack of sufficient scientific correction or truth-seeking against the conventional view. Evolutionary psychological perspectives on development, behavior, and culture run against the orthodoxy within social sciences because they are perceived to challenge deeply held assumptions/convictions about human nature, perfectibility, freedom, and equality.

Definition

The term Blindsight has been coined to describe a seemingly paradoxical clinical phenomenon that arises following injury to primary visual cortex (V1): While patients with Blindsight appear to lack any conscious visual experience, they are sometimes still able to detect visual stimuli when carefully tested (Weiskrantz et al. 1974).

Introduction

Selective lesions of V1 that spare the rest of the brain are rather uncommon in the clinic. Yet several intriguing cases have been described that typically arose from selective traumatic injuries or strokes. Standard clinical tests commonly reveal spatially restricted blindness, also called scotoma, in the part of the visual field affected by the lesion. If the scotoma spans the visual hemifield opposite the affected cortical hemisphere, this type of blindness is often diagnosed as hemianopia. The terms Blindsight or Riddoch-Syndrome were developed in academic contexts (Weiskrantz et al. 1974; Zeki and Ffytche 1998), following careful testing of these patients under rigorous laboratory conditions when these individuals showed residual, V1-independent visual function, yet with no or severely distorted conscious visual experience.

Phenomenology of Blindsight

Blindsight patients typically deny that they have any visual experience inside their scotoma. However, when given certain visual tasks and asked to guess (forced response), these subjects are still able to perform. For example, when a small spot of light is displayed to a visual region that is covered by their scotoma, these patients generally fail to report the presence of any stimulus. However, when encouraged to guess the location of the small light spot, their performance is well above chance and often accurate. In some sense, these patients appear to possess an (unconscious) sense of sight (Weiskrantz et al. 1974; Poppel et al. 1973). In order to understand the nature of this V1-independent visual function, scientists have tested Blindsight patients on a battery of tasks. The broad picture that has emerged from these studies is that Blindsight patients generally perform well on forced response tasks involving salient stimuli that are either very bright or contain motion (summarized in Schmid and Maier 2015; Cowey 2004). Moreover, some patients retain basic visual spatial navigation skills and are able

to walk through a corridor of obstacles. These patients are also able to perform certain eye-hand coordination tasks, such as shaping their hand appropriately for grasping an object inside their scotoma. Some patients are even able to detect certain facial expressions when faces are shown to their scotoma. Blindsight patients are also able to use visual information presented outside their scotoma to solve perceptual completion tasks inside their scotoma. However, residual vision during Blindsight is generally limited to the detection of visual stimuli. When subjects are asked to discriminate between competing object attributes, they usually fail. Even for the case of visual motion, Blindsight patients can successfully detect the presence of a stimulus, but are nonetheless unable to discriminate between different motion directions. Color vision and the perception of shapes seem to be entirely lost following V1 lesions. Animal studies showed that in many mammalian species, such as rats, mice, and cats vision seems virtually unaffected even if the entire primary visual cortex is removed or inactivated. However, this is not true for our closest relatives, as monkeys seem to undergo Blindsight in a similar fashion as human patients.

Blindsight and the Brain Mechanisms of Conscious Perception

Whether Blindsight offers the potential to study (un-)conscious brain function is a matter of intense debate (Zeki and Ffytche 1998; Cowey 2004). Initial concerns that Blindsight merely reflects an experimental artifact arising either from nonspecific light scatter resulting in excitation of lesion surrounding neurons or from incomplete cortical lesions with surviving gray matter islands were dismissed on the basis of tightly controlled experiments. For example, research in macaque monkeys with artificially created lesions demonstrated Blindsight in the absence of any surviving cortical tissue. A second concern with Blindsight has centered on whether subjects are completely unconscious of visual stimuli presented to their scotoma. For example, one

Blindsight patient tested in Zeki's laboratory for residual motion vision reported the sensation of "a moving shadow." Because a similar observation was reported earlier by the neurologist Riddoch, Zeki suggested the term Riddoch-Syndrome as a substitute to Blindsight (Zeki and Ffytche 1998). This and related observations have given rise to a recent trend to differentiate between different Blindsight subtypes (I and II) that differ in their degree of (somewhat) conscious versus (fully) unconscious visual processing.

Neurobiology of Blindsight

Neuroimaging of Blindsight patients has revealed that many visual cortical areas retain some responsiveness to visual stimulation in the absence of input from primary visual cortex (reviewed in Schmid and Maier 2015; Cowey 2004). This kind of V1-independent activity has been shown for area MT, an area that is particularly sensitive to visual motion, as well as for other parts of visual cortex, including object and face-sensitive regions of the brain. These results are only partially consistent with the findings of animal studies. Studies in which V1 was cooled down to temporarily eliminate neuronal activity, repeatedly demonstrated a lack of visual responses in cortical areas outside V1, with the exception of area MT. However, studies in which V1's cortical gray matter was permanently destroyed and animals were tested over longer periods of time, akin to the human injury conditions, have found residual visual responses in a number of visual cortical areas. It thus is likely that neuronal plasticity is an important factor in mediating visual recovery. Indeed, neurons in cortical area V4 that were found to be silent during V1 cooling, regained responses, in particular sensitivity to visual motion, following prolonged recovery after chronic V1 injury. Given these findings of V1-independent activation of higher cortical areas, the question remains how visual information from the retina bypasses (removed) V1 to reach these parts of the brain. Early work in monkeys suggests that the superior colliculus (SC), a small structure in the midbrain that receives direct

retinal input, is critical for V1-independent vision. Inactivation of SC abolished Blindsight in V1 lesioned monkeys and resulted in the elimination of visual responses in area MT. However, there are also direct connections from the retina-recipient visual thalamus (► [Lateral Geniculate Nucleus](#), or LGN and the pulvinar nucleus) to visual cortical areas other than V1. While silencing LGN has been shown to abolish Blindsight behavior and activation of adult visual cortex, pulvinar appears to be of particular importance during development. As SC shares connectivity with both LGN as well as pulvinar, exactly which of these subcortical routes underlie Blindsight remains unclear.

Conclusion

Blindsight is an important phenomenon for understanding visual perception. In particular, Blindsight research has revealed profound insights into the circuitry of the visual system and its ability to reorganize and recover following injury and extensive training.

Blood Sharing by Vampire Bats

Gerald Carter
Smithsonian Tropical Research Institute, Panama
City, Panama

Synonyms

Food sharing in vampire bats; Vampire bat food sharing

Definition

Vampire bats regurgitate food to others in their social group.

Introduction

In many birds and mammals, mothers will regurgitate food to feed their dependent young, but regurgitated food donations among adults have only been reported for the three species of vampire bat (Wilkinson et al. 2016). In the common vampire bat, where this behavior has been most studied, mothers regurgitate food to their pups but will also feed familiar related and unrelated adults (Carter and Wilkinson 2013a, b; Wilkinson 1984). Since it was first reported in 1984, vampire bat food sharing has been a classic example of “reciprocal altruism” or reciprocity — the hypothesis

that helping is adaptive because it promotes reciprocal help.

Vampire bats feed on nothing but blood, typically from large animals such as cows and horses. They feed only once per night, licking about 15 ml from a bite they make with their sharp incisors. Adult bats miss a meal once every 11 nights on average, while young bats miss a meal on almost one third of their nights (Wilkinson 1984). Due to a limited ability to store energy as fat, a vampire bat is likely to starve to death if it fails to feed on more than two consecutive nights (Wilkinson 1984). Regurgitated food donations can therefore save an unfed bat’s life.

Why do Vampire Bats Share Food?

Regurgitated blood sharing likely evolved originally from extended maternal care. Mothers that feed their young this way gain an obvious direct fitness benefit by promoting their offspring’s survival. But females can also gain indirect fitness benefits by feeding other maternal relatives such as their own mothers, granddaughters, or half-siblings. This *kin selection* is possible because females often remain in their natal population. Moreover, successful foragers can obtain a large blood meal, so the costs of sharing are low for the donor and the benefits of receiving are high for the recipient. Since kinship is symmetrical, a simple rule of kin-biased sharing would lead to a symmetrical pattern of helping. For instance, mothers and daughters are likely to each feed the other on different nights whenever one has failed and the other has not. Once this symmetrical helping has been established through kin selection, the direct fitness benefits of receiving reciprocal help contribute more to a donor bat’s inclusive fitness compared to the indirect fitness benefits of aiding the survival of close relatives (Wilkinson 1988). This symmetry will become enforced as *reciprocity* if the bats prefer to invest in food-sharing relationships that yield better reciprocal returns. This scenario predicts that donors share food for two reasons: it aids the survival of close relatives and it helps maintain social bonds that will lead to reciprocal helping when the donor is in need.

This hypothesis is supported by the relative importance of social factors that affect the decisions of vampire bats to share food. Bats target their donations to kin and nonkin that are likely to reciprocate. Despite frequent roost switching, female vampire bats form stable associations with both kin and nonkin, and regurgitations between adults are predicted independently by both kinship and co-roosting association. In the wild, donations among adults occurred primarily between close relatives and only between bats that roosted together at least 60 % of the time. When kin were removed from a group and the unrelated bats were experimentally fasted, they were disproportionately fed by groupmates that they had fed previously (Wilkinson 1984). These results suggest that both kinship and reciprocal help are predictors of food sharing. But what is the relative importance of each?

Long-term captive studies show that reciprocal help is about eight times more important than kinship for explaining the variation in donation rates among familiar individuals (Carter and Wilkinson 2013a, b). Nonkin food sharing was common for long-term associates that first encountered each other as adults, so bats were not “tricked” into thinking all their cagemates were related. Each female bat forms her own fairly consistent network of donors. When one of her primary donors is removed, she receives less food overall compared to when a nondonor is removed; this shows that food-sharing partners in the social group are not interchangeable (Carter and Wilkinson 2015b).

One of the likely benefits of extending sharing to nonkin is that donors can create and maintain more potential sharing partners. Experimental evidence suggests helping nonkin expands the network of possible donors beyond what would be possible if sharing was limited to close kin (Carter and Wilkinson 2015b). When primary donors, mostly maternal kin, were prevented from sharing, females that previously shared food with more nonkin were fed by more individuals and therefore received more food. When kin donors are unavailable, nonkin can therefore act as a safety net.

Evidence suggests that vampire bat food sharing requires enduring social bonds that are also maintained through other cooperative services, such as allogrooming. These stable cooperative bonds are in many ways similar to those found in primates. Compared with other bats, vampires have enlarged brains, especially the neocortex (Baron 1996), a brain region which is linked to social complexity in primates (e.g., Dunbar and Schultz 2007). Vampires are also the only bats known to engage in high levels of social grooming (Carter and Leffer 2015). Social grooming and food sharing are highly correlated in vampire bats (Carter and Wilkinson 2013) and are regulated by at least some shared hormonal mechanisms, including oxytocin (Carter and Wilkinson 2015a). Unlike food sharing, social grooming can occur at any time making it a less costly and more flexible way to invest in a social relationship, and most food-sharing bouts begin with social grooming.

Conclusion

Food sharing in vampire bats illustrates why processes like kin selection and reciprocity should not be considered as alternative adaptive explanations for helping behavior. Instead, these processes are likely to co-occur and interact in groups with relatives, including humans. Reciprocity can occur among close relatives, and indeed it may often require kin-selected symmetrical helping to become evolutionarily stable. Social cooperation is often stabilized by an interactive combination of direct and indirect fitness benefits. A good way to disentangle the evolutionary benefits is to ask: For predicting helping behavior, what is the relative importance of cues to kinship, sex, social rank, past or future cooperation, and the availability of alternative partners?

Body Attractiveness

Viren Swami

Department of Psychology, Anglia Ruskin University, Cambridge, UK

Definition

“Body attractiveness” refers to judgments of the human physical form that excludes facial cues. It could refer to judgments of any human bodily characteristic, either in isolation or as a whole.

Introduction

Evolutionary psychological theories have been used to explain judgments of attractiveness of a range of human morphological traits, typically in isolation of other traits. The aim of this section is not to provide a comprehensive account of all such application of evolutionary psychological theories but rather to provide several key examples, beginning with what is perhaps the most widely cited of such theories: the waist-to-hip ratio hypothesis of women’s body attractiveness.

The Waist-to-Hip Ratio Hypothesis

According to some evolutionary psychologists, a key problem faced by ancestral human populations was the identification of mate value. To overcome this problem, “perceptual mechanisms” are argued to have evolved in ancestral populations to detect and use information conveyed by phenotypic traits in determining an individual’s quality as a potential mate.

Singh (1993) believed that the waist-to-hip ratio – a sexually dimorphic trait – was one such phenotypic trait. Singh also argued that, in contemporary human populations, low female waist-to-hip ratios are reliably associated with improved health and fertility outcomes, and so over evolutionary time men will have evolved to use the waist-to-hip ratio as a direct, universal, and “first-pass” assessment of women’s underlying fitness. To test this idea, Singh developed line drawings of the female form that systematically varied with respect to overall body weight and the waist-to-hip ratio. In a series of experiments using these stimuli, he reported that figures with low waist-to-hip ratios were judged as the most attractive and that ratings decreased with increasing waist-to-hip ratio.

Although the waist-to-hip ratio hypothesis is perhaps the most popular application of evolutionary psychological thinking to body attractiveness, it is also one of the most widely critiqued. For one thing, line drawings have been criticized for lacking ecological validity. In other words, they do not capture the range of body variation that can be perceived in real-life figures and may simplify the way in which real-life judgments of attractiveness are made. When more realistic stimulus sets (including photographs, three-dimensional images, and video clips of real women) have been rated by Western European and North American men, women’s body weight has been found to account for the majority of variance in ratings, whereas waist-to-hip ratio typically explains less than 2 % of variance (Tovée and Cornelissen 2001). These studies suggest that, if men are indeed using women’s waist-to-hip ratios in judgments of attractiveness, it plays a much less important role than overall body size.

A second problem with Singh’s (1993) hypothesis is highlighted by studies that have demonstrated cross-cultural variability in men’s waist-to-hip ratio preferences. Specifically, men from hunter-gatherer and rural sites show a preference for high, rather than low, waist-to-hip ratios, even after controlling for body size (Swami and Tovée 2005a). Other studies have found that men from some subcultures in Western societies, such as

“fat admirers,” also show a preference for high, rather than low, female waist-to-hip ratios. In short, there appears to be a good deal of inter- and intra-cultural variance in waist-to-hip ratio preferences. In view of these problems, some scholars have argued that the female waist-to-hip ratio does not in fact play a direct role in men’s judgments of women’s attractiveness. Instead, the waist-to-hip ratio may be used in judgments of a person’s biological sex when that information is unknown in advance (Johnson and Tassinari 2007). That is, because the waist-to-hip ratio is sexually dimorphic, it may make sense for humans to have evolved to use this phenotypic trait when trying to ascertain the sex of a person. Once this process of social categorization is complete, attractiveness judgments are formed on the basis of additional bodily cues that reflect socio-cultural ideals.

Body Size

As noted above, women’s body size (or body mass index) is one of the strongest predictors of their body attractiveness and explains the majority of the variance in men’s ratings of their attractiveness. While many scholars have relied on socio-cultural theories to explain men’s body size preferences, particularly the idealization of thinness in Western, industrialized societies, this does not discount evolutionary psychological explanations. For example, body size provides a reliable and honest cue of both health and fertility, and humans may have evolved perceptual mechanisms that make use of body size when making judgments of attractiveness. Of course, what is considered an “optimal” body size will vary between populations, and any such perceptual mechanisms may recalibrate as local distributions of body sizes change. As such, instead of expecting uniform cross-cultural preferences for a particular body size, we should anticipate that mate choice vis-à-vis body size will vary depending on local contextual factors. Indeed, the available evidence consistently points to cross-cultural variation in what is considered the ideal body size, with individuals in contexts of

low socioeconomic status consistently showing a preference for heavier body sizes than those from high socioeconomic contexts (Swami 2015).

One specific explanation for this variation, derived from evolutionary psychological theorizing, is that body size provides an honest cue of resource security. This proposition highlights the fact that a primary function of adipose tissue is the storage of calories, which in turn suggests that body fat is a reliable predictor of food availability. In situations marked by resource uncertainty, therefore, individuals should come to idealize heavier individuals, as larger body size would be associated with access to resources. Conversely, thinness in such contexts may be associated with increased incidence of ill health and, in women, lower fertility. Aside from the cross-cultural evidence of an inverse relationship between socioeconomic status (a covariate of resource security) and ideal body size in both women and men, several additional lines of evidence support this reasoning. First, experimental studies have shown that hunger and stress have an effect on men's body size preferences, such that hungry and stressed men prefer a significantly heavier body size than satiated or unstressed men (Swami and Tovée 2012). These findings mirror reports that hunger intensifies selection for a larger body size in some nonhuman species. Second, archival data suggests that heavier body sizes are idealized in American actors and actresses during periods of socioeconomic hardship.

Breast Size

Eye-tracking studies suggest that, when judging the attractiveness of a woman, respondents spend more time looking at the breasts and upper body than any other bodily region. Despite such evidence, the significance of prominent female breasts has proved difficult to explain from an evolutionary perspective, particularly as the human female is the only primate that has permanent, full-form breasts when not pregnant. A number of theories that have been discounted on the basis of lack of evidence include the suggestion that the breast served functional roles such

as milk storage for breast-feeding babies, comfort for nursing infants, and heat stress avoidance. On the other hand, it is possible that biomechanical constraints as a result of sexually dimorphic fat deposition placed unique demands on human female morphology, which resulted in the selection of breasts. Once enlarged, sexual selection may have enhanced the expression of permanently enlarged breasts, with breasts variously argued to act as a sign of age, sexual maturity, or fertility (Barber 1995).

An alternative suggestion is that one function of breasts is to act as an honest signal of fat reserves in non-lactating women, which in turn indicates access to food or resources. This perspective is consistent with the fact that the human breast is partly composed of adipose tissue. Although the amount of adipose tissue varies relative to glandular tissue, human females are unique compared to other species in that the adipose tissue of the mammary gland is situated mainly in subcutaneous and abdominal regions. By contrast, breast size in human female appears to be more strongly correlated with the amount of adipose tissue rather than mammary tissue. In addition, the genetic contribution to human breast size is largely unique to this phenotype and not shared with body mass index. Combined with their prominent display, it is possible that the female breast functions, partly at least, as an indicator of adipose tissue storage. Supporting evidence for this hypothesis comes from studies indicating that hungry men have a stronger preference for larger breasts than satiated men, as well as cross-sectional data showing that men in environments experiencing relative resource insecurity show a stronger preference for larger breasts than their counterparts in contexts of relative resource security (Swami and Tovée 2013).

Men's Body Shape

In terms of men's body attractiveness, it is generally reported that men with low waist-to-chest ratios (or whose torsos have an "inverted triangle" shape) are rated as more attractive than men with

more tubular body shapes (Swami and Tovée 2005b). It has been suggested that low waist-to-chest ratios are indicative of greater mesomorphy or muscularity, which is consistent with the idea that male muscularity enhances ratings of attractiveness. A good genes hypothesis of men's body attractiveness might suggest that men with low waist-to-chest ratios are considered attractive because they are also optimally healthy. However, the evidence does not appear to support this argument. Studies that have included measures of mesomorphy in examining health outcomes suggest that increased mesomorphy is actually a risk factor for ill health. Men's increased body size from muscularity may be associated with higher attractiveness, but it is also associated with poorer health outcomes.

However, there may be advantages of greater mesomorphy which offset complications associated with health and well-being. For example, increased muscularity may intimidate rival men (detering them from making cuckoldry attempts) or provide enhanced defensive abilities. In such a scenario, the health costs of developing increased muscularity may be outweighed by their benefits, which may also be passed on to offspring. In a similar vein, Barber (1995) has suggested that women may have evolved to find men with a certain physique attractive because this body shape was beneficial to men in past evolutionary history. For example, it is possible that a low waist-to-chest ratio, which is associated with physical strength and upper-body muscle development, was an adaptation for intrasexual competition among men in evolutionary history, either via direct fighting or through intimidation.

Conclusion

While the focus of this section has been on waist-to-hip ratios, breast size, waist-to-chest ratios, and body size, it should be noted that evolutionary psychological theories have also been applied to a number of other morphological traits. For example, evolutionary psychologists have also proposed theories to account for the attractiveness of leg-to-body ratios, body hair, height, skin

tone, body symmetry, and foot size, among other characteristics (Swami and Furnham 2008). What is clear from this research is that there are a multitude of factors that shape attractiveness judgments, and an important direction for future research is the development of meta-theoretical perspectives that are able to combine distal, evolutionary factors with more proximate sociocultural factors. In addition, it will be important for scholars to consider morphological traits as a whole rather than in isolation.

The role of body fat and its distribution in sexual selection

Introduction

White fat is the body's main energy store and is deposited in two main reservoirs: as visceral fat in the abdomen and as subcutaneous fat on the thighs and buttocks. The visceral component of abdominal fat is more detrimental to long-term health than subcutaneous fat. This may be for partly mechanical reasons; the deposition of fat around the organs in the abdominal cavity may interfere with their normal function. Additionally, the development of insulin resistance (which contributes to diabetes and vascular disease) is attributed to an adipokine called retinol-binding protein 4 (RBP4), which is generated by fat cells. Visceral fat generates greater amounts of RBP4 than subcutaneous fat, and so visceral fat potentially has a disproportionate impact on health.

The distribution of fat on the body differs between the genders. Men and women produce both testosterone and estrogen. It is the relative balance of the two which determines fat distribution. In women, the higher level of estrogen mediates the distribution of fat primarily onto the thighs and buttocks as subcutaneous fat deposits. In men, the higher level of testosterone promotes fat deposition in the abdomen as visceral fat. Thus, it is possible that lower body shape (reflecting this pattern of fat deposition) could be a cue to relative hormone levels. This is usually indexed by the circumference of the waist divided by the circumference of the hips (the waist-to-hip ratio or WHR). A lower WHR (i.e., a more curvy lower body) could potentially signal higher estrogen levels, and a lower WHR (around 0.7) has been linked to a more successful outcome in artificial insemination procedures. It is also potentially a cue to health due to the link between visceral fat and type 2 diabetes and hypertension.

The most commonly used measure of overall body fat is the body mass index (BMI). This is a measure of weight scaled for size, or more precisely it is the subject's weight (Kg) divided by the square of their height (m²). Although BMI is generally a good measure of body fat in population studies, it does have some limitations on an individual level. The measure assumes that individuals have the average proportion of muscle to fat. Thus, it overestimates the fat level of someone who has an above average muscle content for their weight (such as an athlete) and underestimates the fat level of someone who has an above average fat content (such as someone with a more sedentary lifestyle). Despite these shortcomings, BMI is still the most widely used measure of body fat due to its ease of use and its noninvasive nature (Table 1).

People can be separated on the basis of BMI into several categories. The BMI range of 18.5 to 24.9 is the healthiest range and is often also called the "normal" BMI range although this is a misnomer. In many Western industrial societies, such as the United States, the normal or average BMI is actually in the overweight BMI range, as the increased consumption of cheap high calorie food and reduced manual labor have led to a

Body Fat Percent and Distribution, Table 1 The World Health Organization (WHO) classifications of BMI categories

made by 40 male subjects on each image. Regression lines (*solid line*) and their 99 % confidence limits (*dotted lines*) are superimposed (Redrawn from Tovee et al. 1999)

general increase in body weight across the population. Additionally, there are ethnic differences. For example, the upper limit of the healthy BMI range is 22.9 for people of Chinese and South Asian origin. This is because for a given BMI, Chinese and South Asian people have a significantly higher proportion of their mass made up from body fat, and most importantly, a significantly higher proportion of it is stored as visceral adipose tissue in the intra-abdominal cavity.

The BMI categories are very broad divisions, although the central BMI category is referred to as the healthiest category. This does not mean all the values within this category are equally healthy. Longitudinal epidemiological studies suggest that a BMI value of around 20 to 21 is the optimal value in Western Caucasian populations for health and long-term survival.

The Role of Body Fat in Mate Selection

Singh (1993) hypothesized that because WHR potentially provides information about

reproductive status and long-term health risks, there are good evolutionary reasons to expect WHR to be used in attractiveness judgments and mate choice. The role of WHR in attractiveness was supported by studies that asked observers to rate sets of either line-drawn figures of women's bodies (e.g., Singh 1993) or altered photographic images (e.g., Streeter and McBurney 2003). In these studies WHR is manipulated by altering the width of the waist of the figures. The results from such studies have led to the conclusion that a WHR of approximately 0.7 is most attractive with higher (i.e., less curvaceous) WHRs being rated less attractive by Western observers. However, altering the width of the waist not only changes WHR but also apparent BMI. As WHR rises, so does apparent BMI, making it impossible to say in these image sets whether changes in attractiveness are due to WHR, BMI, or both (Tovee and Cornelissen, 1999). An additional problem with these studies is that some of the manipulations may result in images outside the natural range of variation and as a result lack ecological validity (Fig. 1).

To overcome these shortcomings, a number of studies have been carried out using digital photographs, 3D scans, or videos of women's bodies which show a degree of independence in their BMI and WHR variation, and these studies suggest that BMI is the primary predictor of attractiveness judgments (e.g., Tovee et al. 1999; Fan et al. 2004; Rilling et al. 2009). However, under normal circumstances, BMI and WHR covary in Caucasian populations. For example, the Health Survey for England, which includes directly obtained measurements from 1808 Caucasian women of reproductive age (16–45) ranging in BMI from around 15–45, shows a correlation between BMI and WHR of 0.45. For studies of attractiveness, the correlation between features such as BMI and WHR raises the problem of collinearity among explanatory variables and raises the question of whether WHR or BMI is the primary cue used in attractiveness judgments.

In an attempt to address this problem, Singh and Randall (2007) asked observers to rate the attractiveness of pre- and postoperative photos of women who had plastic surgery to redistribute fat from around the waist to the hip and buttock regions. It is suggested that this reduces WHR without significantly changing BMI. Postoperative photographs were judged as more attractive than preoperative photographs. Singh and Randall concluded that WHR is a key predictor of female attractiveness, independent of any effect of BMI. However, the view of the women in the images was restricted to a back or oblique view of their lower torso and upper thighs only. So, given that the relative size of the waist and hips was the only information available to observers, it is perhaps not surprising that their preferences were affected by WHR. The question remains as to how these women would have been rated if the whole body had been visible to observers. Moreover, both behavioral and eye movement studies suggest that the degree of stomach depth (i.e., the degree to which the stomach protrudes) is used as the primary cue to judge BMI. This surgical intervention, which artificially alters this part of the body, may lead observers to perceive a difference in BMI in the

before and after condition. This is important because the observers have only the visual image to go on, and if the image appears to vary in BMI (even if there is no significant change in the BMI of participants in the photographs), then the observers will react to the images as though they do alter in BMI. Thus, the apparent BMI and WHR of the pictures may covary, and it is not clear whether the reported changes in attractiveness ratings were due to changes in WHR, apparent BMI, or some mixture of the two.

An obvious solution to this problem is to simultaneously record observers' eye movements while they make perceptual judgments. Although human eyes can attend to a visual field of around 200°, detailed information can only be received from a central region of around 2°, corresponding to the fovea. As a result, the information in a picture can only be sampled in discrete “bite-sized” chunks corresponding to the observer's current fixation position. Thus by tracking an observer's fixation position, it is possible to gain a direct measure of which regions of an image are being sampled at any one time and therefore which regions are likely to be contributing information to the perceptual judgments.

Therefore, Cornelissen et al. (2009) recorded the eye movements of three groups of male and female observers when they rated a set of 46 photographs of female bodies. The first group of observers rated the images for attractiveness, the second group rated for body fat, and the third group rated for WHR. If either WHR and/or body fat is used to judge attractiveness, then observers rating attractiveness should look at those areas of the body which allow assessment of these features, and they should look in the same areas when they are directly asked to estimate WHR and body fat. So it is possible to compare the fixation patterns for the explicit judgments with those for attractiveness judgments and infer which features were used for judgments of attractiveness. As can be seen in Fig. 2, observers' fixations for attractiveness and body fat clustered in the central and upper abdomen and chest, but not the pelvic or hip areas, consistent with the hypothesis that WHR had little influence over attractiveness judgments. The pattern of fixations

Body Fat Percent and Distribution, Fig. 2 Contour plots of the fixation distributions for observers making (a) attractiveness, (b) body fat, or (c) WHR estimations overlaid onto the image of the reference body. In order to facilitate inspection of the data across all judgments,

fixation density in the left and central columns has been converted to a percentage score, indicated by color bars (0–100), with red indicating the highest density (Redrawn from Cornelissen et al. 2009)

for attractiveness ratings was very similar to the fixation patterns for body fat judgments, but the fixations for WHR ratings were significantly different from those for attractiveness and body fat suggesting WHR was not being used in attractiveness judgments.

In an alternative, Crossley et al. (2012) used a 3D interactive software system which allows participants to produce a photorealistic, virtual female body with their ideal size and shape. Both male and female participants created a slim body with a low BMI value of 18.5 (at the lower end of the “normal” BMI range). As part of the shape charges, both male and female participants also narrowed the waist which also altered the WHR. To test whether the shape change was purely an effect of creating a low BMI body or represented a choice for a more curvy body as well, Crossley et al. modeled the expected way that shape should change as BMI decreased, and they found a significant deviation in shape from this expectation. This suggests that WHR does

play a small but significant role in attractiveness preferences which is independent of BMI.

Cross-Cultural Judgments

If overall body mass honestly signals an individual’s health and reproductive potential and a specific value of this feature signals optimal health and fertility, it follows that in environments where the optimal values for these features differ due to differences in environmental pressures, the attractiveness preferences should also be different. Moreover, as observers moved from one environment to another, it would be adaptive for them to alter their attractiveness preferences to those that accurately reflected optimal health and fertility in their new environment. This seems to be the case for people of the same ethnic group, living in different socioeconomic conditions; people of lower socioeconomic status (SES) preferred bodies of a higher BMI than those of a higher SES

(Swami and Tovee 2005). Additionally, Zulu migrants moving from a low SES environment (rural South Africa) to Britain (relatively high SES environment) modify their preferences toward those of people in Britain (Tovee et al. 2006). This suggests that these preferences are part of a flexible behavioral repertoire, acquired through social learning, which allows humans to adapt and respond to changing conditions within an environment or when moving between environments. In this case, the change in preferences is likely to be mediated both by social interactions and the media environment. The Western media emphasize a preference for a slim and shapely body as the female ideal, and the ubiquitous nature of this ideal in television, magazines, and advertisements is likely to accelerate the putative changes to body size preferences (Boothroyd et al. 2016)

Conclusion

Both the amount and distribution of body fat are important predictors of health and fitness, and both body features have been linked to attractiveness judgments. Overall fat content (usually indexed by BMI) seems to be used as the primary cue to physical attractiveness judgments, and this may be because the covariation of overall fat and its distribution means that choosing a particular body mass will also tend to be choosing a particular body shape. However, body shape (as indexed by WHR) is also a significant independent predictor of attractiveness independent of body mass and may be used in fine-tuning judgments between bodies of a similar BMI.

Definition

The deliberate or purposeful alteration to the human body/anatomy.

Introduction

Body modification is a more permanent form of human ornamentation. Forms of body modification include corseting, piercing, tattooing, subdermal implants, and ear gauging. Perhaps most common in Western culture is piercing – particularly the ears. Other, commonly pierced

areas include the nose, tongue, lip, eyebrow, and even the genitals. Tattooing is a form of *permanently* ornamenting the body with artistic pieces via ink inserted into the skin with a needle. The Maori and other Western Pacific cultures have a rich history of ornamenting their bodies via tattooing. Today, tattoos are widely accepted multi-cultural phenomena across the world. This is a very interesting human universal.

Another type of body modification that has gained popularity is ear gauging in which an individual slowly stretches a hole in their ear (typically in the ear lobe) over time. Larger jewelry is gradually placed in the hole, occupying the space and allowing the ear to heal around the jewelry. The size of gauge (hole) can vary from the size of a needle to the size of a small fist.

Within certain populations and during specific historical time periods corseting was a widely practiced custom in which a female would squeeze her waist into a metal-ribbed bodice that remained tightened throughout the majority of the day. The figure that was implied through the artificial tightening of the corset is thought to mimic that of a 0.7 waist to hip ratio, which is thought to signal reproductive fitness. The use of this method was typically very painful to the individual and often resulted in organs being forced into different parts of the torso. Within the last year “waist training” has re-gained popularity, interestingly, with the Kardashian family at the helm of the movement. Though modern waist training is not as archaic as past methods, it still presents a similar evolutionary cost vs. benefit ratio in which an individual is essentially risking their health to appear attractive (by certain standards).

Extreme Modification

Extreme body modification takes this cost versus benefit ratio a step further. Subdermal implants (insertion of material under the skin) are one of the more common forms of extreme body modification. The areas that individuals get enhanced vary widely, but a common area is the forehead where horn shapes can be suggested through modification. Some individuals use this

form of modification for sexual enhancement. Males can get a procedure referred to as “pearling” in which bio material is inserted under the skin of the penis systematically to make it have a permanent “ribbed” sensation.

Another form of extreme modification is tongue splitting, where the tongue is split down the middle (by either cutting or binding over time), resulting in two useable half portions of the tongue – if the procedure is a success and infection is avoided. In fact, this procedure is highly risky, and if not done correctly, individuals can lose their sense of taste or even their ability to use the muscles in their tongue. Other extreme forms of modification include ear pointing (where the tips of the ears are pointed to mimic elves from fantasy novels), eyeball tattooing (tattooing the whites of the eyes), and even *extraocular* jewelry (where a small piece of jewelry is inserted under the sclera and over the white of the eye).

One of the most novel forms of body modification is in the form of *biohacking*, where a magnet placed under the skin allows the individual various benefits based on the type of procedure. Some magnets allow individuals to become sensitive to magnetic fields in their environment; others alert individuals to when they are facing north by moving slightly, or RFID chips allow individuals to open doors, computers, or even safes.

Evolutionary Implications

From an evolutionary perspective, body modification is particularly fascinating because it would seem that the potential costs of infection/nerve damage/scarring outweigh the benefit of appearing attractive to potential mates. Essentially, body modification – including extreme body modification – is a complex form of costly signaling.

Definition

Body posture refers to the way that the body is positioned, including whether one is standing or sitting, the relative positions of body parts, and how much space the body occupies. Body posture is a form of nonverbal communication.

Introduction

Body posture can be used to communicate information, intentions, and emotions without the need to produce speech. Body posture is informative about emotional states (Niedenthal 2007), and it has been shown that people are better at identifying facial displays of emotion when these are paired with congruent body postures (Mondloch et al. 2013). Furthermore, posture can modulate one's own emotional experiences. For example, Stepper and Stack (1993) found that participants who received good news while adopting a slumped posture felt less proud and had lower mood than participants who received the same news while their head and shoulders were held high and straight.

This section explores ways in which dominance is expressed through body posture, the evolutionary purpose of postural cues of dominance and their physiological underpinnings, and finally how these cues influence behaviors such as mate selection. Dominance here is defined as the actual or perceived power of individual(s) over others. Postural indicators of

dominance include adopting open and erect stances (Darwin 1872/2009) and actions such as placing the hands on the hips and jutting out the chest. Postures that increase the amount of space an individual occupies also signal dominance. In contrast, closed, contractive body postures signal submissiveness and powerlessness.

Dominance, Posture and Behavior

The Evolutionary Benefits of Dominance and Dominant Behaviors

In the introduction, dominance was defined broadly as the actual or perceived power of individual(s) over others. Why is power desirable? Powerful individuals tend to have a greater sense of control over their mind and body, as well as greater access to resources in society. At first it may appear that exhibiting dominant cues is only beneficial to the dominant individual. However, individuals within social groups often rely on one another to achieve goals and maintain social stability, and power relations are key to this process. In our evolutionary past, it is likely that violence and aggression were used to establish dominance. Nonverbal communications of dominance may therefore have evolved to signal to non-dominant individuals that challenging the dominant individual's authority could have negative consequences and may even lead to violence. This would deter others from challenging the dominant member of the group and lessen the likelihood of violence or social unrest. Thus postural indicators of dominance not only benefit the dominant individual but may also serve the purpose of defining and maintaining power relations which minimize conflict within social groups. For an example from the animal kingdom, consider that in over 500 h of observation, Hall (1964) did not report one violent encounter between male Patas monkeys (*Erythrocebus patas*) in a social group despite noting a number of aggressive threats and bodily cues signaling dominance. In humans, Schaal et al. (1996) reported that young boys who were perceived as dominant were able to impose their will on others

while maintaining social attractiveness, whereas physically aggressive or violent young men were not socially dominant. Thus nonverbal dominant cues likely evolved, at least in part, to maintain social stability and minimize violence within social groups.

Hormones: The Physiological Basis of Dominance

Are there any physiological markers of dominance? The hormone testosterone has been associated with feelings of dominance and power. For example, engaging in dominant behaviors increases testosterone levels. Mazur and Booth (1998) reported that testosterone levels tend to increase in anticipation of competition (whether aggressive or nonaggressive). Furthermore, testosterone levels tend to rise in winners and fall in losers after a competition (Mazur and Booth 1998). Thus testosterone both drives and responds to competitive and dominant behaviors. In addition, Schaal et al. (1996) found that higher levels of testosterone in young men were associated with perceived social dominance.

The hormone cortisol, which has been associated with feelings of stress and submissiveness, may compliment testosterone. Supporting this, Carney et al. (2010) found that the relative levels of testosterone and cortisol are modulated by body posture. In one study, they reported that participants who adopted high-power poses (open, expansive postures which signal dominance) for 2 min (two poses were held for 1 min each) showed an increase in testosterone levels and a decrease in cortisol levels. In stark contrast, participants who adopted low-power poses (small, contracted postures which signal submissiveness) for 2 min showed a decrease in testosterone levels and an increase in cortisol levels. Thus dominant postural cues may serve the purpose of maintaining social stability and minimizing violence by communicating caution to others, and this appears to be facilitated at the physiological level through immediate and direct effects of posture on the hormonal state of both dominant and non-dominant individuals.

Behavioral Consequences of Dominant Cues: Mate Preferences and Selection

Postural cues of dominance can influence mate selection. It has been suggested that masculine and dominant men are more sexually attractive to women (Sadalla et al. 1987), and thus displaying dominant postural cues may improve mating success for men. For example, Ahmetoglu and Swami (2012) reported that both introverted and extroverted women rated men with open body posture and gesticulation as more attractive than men with closed body posture.

It has been further suggested that fertile women prefer dominant men. In a recent meta-analysis, Gildersleeve et al. (2014) assessed the evidence for the ovulatory shift hypothesis (Gangestad et al. 2005), which suggests that women are more attracted to men who they perceive to have characteristics which reflect higher genetic quality – including dominance – on high-fertility days during their menstrual cycle than low-fertility days.

Given this natural fluctuation in how attracted women are to dominant men across the menstrual cycle, behaviors which alter this cycle may have consequences for mate choice. One such behavior is the use of the contraceptive pill. For example, Penton-Voak et al. (1999) found that women who were taking the pill showed weak or no preference for vocal or facial masculinity. Alvergne and Lummaa (2010) reviewed evidence which showed that using the pill can affect a woman's attraction to men and interfere with her ability to select a preferred partner. For example, they highlighted that without the natural fluctuation in attraction to masculine and dominant cues, women who take the pill may choose partners who are less genetically different from themselves. This means that the children of pill users may be less heterozygous which could lead to poorer immune function and diminished perceived health or attractiveness (Alvergne and Lummaa 2010; Roberts et al. 2005). However, the specific implications of behaviors such as pill use and major life events such as childbirth on attraction to dominant cues and mate choice are not yet fully understood.

Conclusion

In summary, body posture broadly refers to the spatial relations between body parts, the positioning of the body, and how much space the body occupies. Posture can communicate emotions to others and also modulate our own emotional experiences and behaviors. Hormones play a role in facilitating the relationship between body posture, emotions, and behavior. Specifically, changes in posture have been shown to be accompanied by changes in the relative levels of testosterone and cortisol (Carney et al. 2010), two hormones which are associated with dominant and submissive behaviors, respectively. Men who are perceived as dominant but do not engage in violent behavior are capable of exerting power over others in their social group while still being seen as socially attractive (Schaal et al. 1996). Thus dominant postural cues may serve the evolutionary function of preserving social stability by maintaining power relations which deter violent or dissenting behaviors from nondominant individuals. Dominant postural cues also have consequences for mate choice since, according to the ovulatory shift hypothesis (Gangestad et al. 2005), women are more attracted to dominant men during times of high fertility. By altering hormonal levels and eliminating this natural fluctuation in attraction to different men, behaviors such as taking the contraceptive pill may have consequences for mate choice and the health outcomes of future children (Alverge and Lummaa 2010; Roberts et al. 2005), but research in this area is still ongoing. To conclude, dominant body posture can be used to communicate emotions and has important consequences for the short-term experience of one's own emotions and experiences. Dominant body posture can also influence longer-term choices including selecting a mate.

Body Reserves and Food Storage

Andrew D. Higginson

Psychology, University of Exeter, Exeter, UK

Synonyms

Energy balance; Fat; Feeding; Obesity; Overweight

Definition

The decision controlling consumption of food and storage of nutrients in the body.

Introduction

Humans, just like other animals, are adapted to store nutrients in their body. Body reserves consist of fat, glycogen, and other nutrients, but the storage of fat is most usually considered, not least as part of the effort to understand and so treat obesity. The health issues caused by obesity make understanding the evolutionary reasons that people become overweight urgent. Researchers have advanced several hypotheses for people becoming overweight, and there remains controversy about the important selective pressures that must be incorporated in models of energy storage.

Theories of Appetite and Obesity

The mammalian body stores energy in the form of lipids and glycogen. There are no significant stores of protein, although muscles and organs can be broken down for energy during starvation. Minerals and vitamins are stored in small amounts. When the energy contained in the digestive system is exhausted, glycogen stored in the liver and muscle is used. Only after that is fat used (McCue 2010). However, fat is an highly energy

dense substance and constitutes the vast majority of the calories stored in the body of most animals (Wells 2010).

Fat has many roles in animals (Pond 1998). Known advantages of stored fat include as a source of energy when food is not available or cannot be eaten (migration, breeding, hibernation, winter). There are fat stores close to lymph nodes to provide immediate fuel for the immune system. Fat stores in human females, or at least their location, are under sexual selection because it exaggerates body shapes associated with fertility, or the ability to supply lactation for infants. For some animals, especially cetaceans (dolphins and whales), fat is an insulating material; however, at human levels the heat conservation effect of fat is negligible. Researchers have predominantly focused on the role of fat as an insurance against the inability to find food, such as in famines. Therefore, there has been a focus on the incidence of famine, and mortality associated with famine, during human history (Speakman 2006; Prentice et al. 2008).

The prevailing viewpoint is that body reserves are controlled by a system shaped by natural selection so that the evolved behavior is adaptive – that is, enhances the ability to survive and reproduce. It is therefore surprising that eating behavior often results in obesity in humans and associated animals. Much research effort in to body reserves has had the main objective of explaining human susceptibility to obesity. There are many proposed hypotheses for obesity, many invoking physiological mechanisms that are maladaptive in modern environments with evolutionarily novel food stuffs (Speakman 2013).

Following *Tinbergen's Four Questions* (Tinbergen 1963) proposed hypotheses can be categorized as proximate or ultimate. The former focus on physiological or psychological mechanisms that cause fat storage or over-eating. The latter propose how an eating and fat storage system may have been designed by natural selection such that it drives obesity in a modern environment. While they are often considered to be competing hypotheses, mechanistic hypotheses can explain *how* an ultimate explanation is

implemented. For example, an urge to consume sugary and fatty foods during winter festivals – such as Christmas – is a mechanism that implements the storage of extra fat in case of food shortage that would happen in winter in evolutionary history. This entry focuses on those hypotheses that take evolutionary and/or psychological approach, either by discussing psychological mechanisms or by predicting how an energy balance system would be designed by natural selection.

Avoiding Starvation

The thrifty genotype hypothesis proposed that humans, having evolved in unpredictable environments, are genetically predisposed to eat excess food in times of plenty, so that they have sufficient stores for times of need (Neel 1962). Eating whenever food is available in the modern Western environment of “continuous feast” can lead to obesity. There is evidence that body fatness or the drivers of it are heritable; one study showing that around two-thirds of the variation in BMI can be attributed to variation in genes (Allison et al. 1995).

It is clear that individuals do not gain weight indefinitely, but tend to defend a defined level of energy reserves: however heavy people are, their weight tends to be fairly constant over time. This observation underpins the set-point model of the control of adiposity, which supposes that the body has a target level of fat (Kennedy 1953). This idea was supported by the discovery of the role of the hormone leptin, which is produced by lipid-storage tissues and inhibits appetite (Zhang et al. 1994). The set-point model compares intake control to a system like a thermostat: if energy reserves are below a given threshold, the animal eats; if above that threshold, the animal does not eat. Since the change in body mass can be determined by the energy-balance equation of energy intake minus energy expenditure, it is possible to lose fat either by decreasing intake or increasing expenditure.

A challenge to the thrifty genotype hypothesis has always been the great variability within human populations in fat storage, with most individuals able to resist the supposed urges from their

genes with variable success in obesogenic societies (Speakman 2014). An idea that attempted to address this challenge is the thrifty phenotype hypothesis, which suggest a thrifty phenotype is not genetically determined but may be induced by experiences early in life (Barker 1997). For instance, there is some evidence that obesity in pregnancy leads to larger birth weight via greater levels of glucose in the mother’s blood (Tyrrell et al. 2016). Adverse effects may be “interpreted” by the baby’s systems as a challenging environment leading to the greater storage of fat (Wells 2007). However, maternal effects are insufficiently strong to alone explain the incidence of obesity.

The doubts about these various assumptions required for the thrifty genotype hypothesis lead to consideration of how the genome may underlie obesity via other mechanisms. The thrifty-epigenotype model (Stöger 2008) proposes that selection has led to metabolic thrift being highly conserved due its importance. This would explain why while there are many genes indicated in determining body weight, they are all of small effect. Epigenetic effects – such as DNA methylation – caused by food shortage in the distant past have been preserved in modern people. In other words, this is a merging of the thrifty genotype and phenotype hypotheses.

The food insecurity hypothesis (Nettle et al. 2017) is an extension of the thrifty models that explains the greater incidence of obesity among lower socio-economic groups by suggesting that uncertainty in one’s environment in terms of money (resources for acquiring food) triggers an increased investment in insurance. Consideration of the thrifty epigenotype model may explain the deviation from predictions: if an individual’s socio-economic status differs from that of their parents then they may not have the expected level of obesity.

More recently (Speakman 2018), Speakman has proposed that the selective pressure to store fat is not from starvation risk but from the risk of dying from disease if body reserves are low. This occurs because pathogens induce under-eating leading to weight loss during illness. Pathogen-induced anorexia by being an enforced restriction

on food intake, from the viewpoint of evolutionary models of energy balance, is identical to famine. However, this viewpoint does not suffer from the objection that famines, or deaths during famines, are insufficiently common to exert sufficient selective pressure to maintain thrifty genes. It also means that it is possible for an animal to starve to death while external food supplies are still abundant.

Mechanistic Models

Effect of environmental factors on the target fat level suggests a different perspective that focuses on individual mechanisms. These mechanisms combine to result in a certain level of fat, an idea known as the settling point model (Wells 2010). This proposes that the body reserves level is not under active control, but is a consequence of the balance between energy expenditure and energy use. A heavier body has greater costs so weight gain can be somewhat self-limiting, but the weight settled on depends on extrinsic factors such as food quality and opportunities to exercise.

There will be evolved mechanisms that affect food intake and energy expenditure, and selection acts on the outcomes of their interactions. From this viewpoint, the settling point model is focused on mechanisms that could combine to achieve a set point, without any need for the set point itself to be stored in the system. Thus, these proposals are not mutually exclusive, but are at different types of answer *sensu* Tinbergen's Four Questions.

Some specific mechanisms have been proposed. In modern environments people consume more highly processed, carbohydrate-rich food that quickly increase glucose levels in the blood. The carbohydrate insulin model predicts that the consumption of carbohydrate leads to insulin spikes which prompts more eating and lower activity to preserve fat, and that this is excessive so overall weight is gained (Ludwig and Ebbeling 2018). However, mice do not show increased food consumption in response to insulin nor reduce their activity (Ludwig and Ebbeling 2018).

The hedonic over-ride hypothesis posits that sugars and fats are so strongly rewarding that the energy consumption control systems are

overwhelmed, leading to weight gain (Berridge et al. 2010). By comparison to the effect of simulant drugs, it has been suggested that the reinforcement may even lead to food addiction (Gearhardt et al. 2011). Evolutionarily such strongly rewarding responses make sense because rich foods would be relatively scarce, and so there is little selective pressure to avoid becoming addicted.

The protein leverage hypothesis focuses on the other side of the consequence of an increase in carbohydrate-rich foods: the reduction in the relative amount of protein. Because a smaller proportion of food, especially meat, is protein, people have to eat more to get their protein requirement. Protein is not stored by the body but may still play an important role in determining body reserves of energy. The protein leverage hypothesis states that obesity results from a simple rule to eat the correct amount of protein, applied when the ratio of protein to carbohydrate + fat of food is reduced as in the modern Western diet (Simpson and Raubenheimer 2005). There have been many tests of this hypothesis by constraining the macronutrient content of animals in the laboratory, with strong support for the idea that a protein target when protein supplies are constrained leads to over-eating (Raubenheimer and Simpson 2019). However, others have found that if the protein to fat ratio and the availability of lipid are both altered then the amount of lipid may be driving previous results (Hu et al. 2018), although studies on other species do not necessarily undermine the hypothesis that protein leverage may drive obesity in humans (Raubenheimer and Simpson 2019).

Optimality Models

While ideas of set points have long been considered, the selective pressure that acts to push down the set point has been neglected. The probability of starvation decreases as the storage of fat increases. So in the absence of all other pressures, it would be best to store as much fat as possible. That humans and other animals do not suggests that there are costs associated with fat storage. By understanding why animals are not always as fat as possible, we might be able to predict the variation within populations.

Progress in understanding fat storage has frequently followed from research on the adaptive use of energy reserves by animals. Such models are common in behavioral ecology in which energetic reserves mediate the trade-off between various fitness-enhancing activities, such as feeding, courting mates, and being vigilant. These models successfully predict the behavior of animals by assuming that their behavior is optimal for any given level of reserves, such as when and which foods animals should consume (Houston and McNamara 1999). Such models typically use optimization, predicated on the conception that natural selection is an optimizing algorithm that should result in animals making appropriate responses to conditions (Stephens and Krebs 1986).

This research has shown that the amount of fat stored by animals is not a direct consequence of availability and expenditure but is strategically regulated (Macleod et al. 2005; Macleod and Gosler 2006; Bonter et al. 2013). This research is mostly based on small birds. One might expect that animals would be fattest when food was easiest to find. Actually, birds are fattest in winter when food is scarce and/or the ambient temperature low and so metabolic expenditure is high (Rogers 1987; Grubb and Pravosudov 1994). This predicts that individuals killed by predators (or disease) are the leaner ones, as they forage more, or take more risks, in order to gain weight.

One type of cost is intrinsic: carrying fat has energetic consequences, locomotion takes more energy when a body is heavier. The other type of cost is extrinsic: locomotion may be slower when a body size heavier, which may reduce the ability of predators to catch their prey and for prey to avoid being caught by their predators. If the risk of predation when foraging is greater than the risk when not foraging, or if there are energetic costs of carrying fat then there will be some limit on fat storage. This limit will be lower if foraging is more energetically costly than not foraging, such as due to locomotive costs (Houston and McNamara 1999). The need to conserve fat by reducing demands has been suggested to be the reason that during starvation protein catabolism starts well before fat reserves are exhausted:

reducing muscle mass reduces energy consumption and so prolongs survival (Higginson et al. 2014).

Neutral Selection

In attempting to explain the variation in body weight, Speakman has proposed the ‘drifty genotype’ hypothesis (Speakman 2008), based on the idea that it has been the removal of predation risk that leaves humans vulnerable to obesity. This hypothesis is based on a model of body reserves (amount of fat and other energy stores) control that imagines there is not one but two critical reserves levels, labeled “thresholds.” The lower threshold causes the animal to increase reserves so it is not in danger of starving. The upper threshold causes the animal to decrease reserves to avoid predation due to reduced maneuverability. If reserves are between the thresholds, there is no intervention and reserve levels vary according to environmental drivers, such as food supply. In this way, the dual-intervention point model combines the ideas of (genetic) set-points responding to evolutionary pressures and settling points – controlled by environmental triggers – that act between the intervention thresholds. It is proposed that the virtual elimination of the risk of predation on ancestral humans meant there is no selective pressure on the upper threshold. Genetic drift in the genes that control the upper threshold has resulted in the wide range of body sizes we observed today, because different genotypes have moved random amounts.

This genetic drift means that there would have been no recent selection on genes that control adiposity, in contrast to the thrifty genotype hypothesis, which assumes that the risk of starving in a famine selects for high BMI. Recent analysis of selection on the genes that have been associated with BMI has failed to find such evidence of strong selection (Wang and Speakman 2016), as assumed by the drifty genotype hypothesis.

When originally proposed the dual intervention point model did not include an explanation for why the animal is indifferent to the level of reserves if they are between the thresholds. If intervention is costly (i.e. searching for food),

then it would be better to be further from the threshold than near the threshold. The animal can only be indifferent to the level of reserves if the long-term survival is constant between the thresholds, which can only occur if both predation risk is constant if reserves are below the upper threshold and the risk of starvation is constant above the lower threshold, or if between the thresholds the increase in one is exactly cancelled out by the decrease in the other.

One implementation of a dual intervention point model (Higginson et al. 2016) was an attempt to understand how it could be adaptive to have two thresholds. Assuming a cost to switching between weight gain activity that incur predation risk and a weight losing activity at lower risk, the optimal strategy is to have two thresholds. However, the location of these two thresholds depends on both the starvation risk and the predation risk, so both would move.

In answer to this criticism Speakman (2018) presented an explicitly mathematical description of the dual intervention-point model, based on the role of uncertainty in the body “knowing” how much energy is currently stored. This model was based on the standard behavioral ecology models of an increasing rate of predation and a decreasing rate of starvation (due to pathogen-induced anorexia during illness) as body fatness increases. If both functions are convex, then the total mortality is a U-shape. Under the assumption that the system is fairly insensitive to small changes in fat level, the system would not intervene provided reserves were around the bottom of the “U”. The intervention points are set by natural selection to be around the point that the mortality increases steeply.

For this system to result in widespread fat levels (from lean to morbidly obese), the thresholds have to be controlled by independent genes, allowing the upper threshold to drift while the lower threshold remains constant. Genes do not code for outcomes but for mechanisms that cause outcomes and further developments to this hypothesis will need to focus on the mechanistic explanation *sensu* Tinbergen’s 4 Whys: That is, to establish *how* the system implements the loss of body reserves when the upper threshold is

exceeded in a way that does not affect behavior and outcomes at lower levels of reserves. For instance, to stop gaining weight at the upper threshold the hedonic response to food must be switched off and the response to high lipid stores be strong. At the lower threshold, the opposite is true. Developments to the theory need to address how the mechanisms that control feeding behavior, including hormonal feedbacks from lipid stores and hedonic responses to food, would be independently determined by different genes.

Exploiting Gluts

The focus of research on evolutionary explanations for obesity has assumed that the positive selection pressure for storing fat is the insurance against food shortage, particularly famines. There has long been debate over whether famines are sufficiently common (Speakman 2006; Prentice et al. 2008). But storing energy allows animals to avoid looking for food when it is risky or less profitable. For instance, passerine birds avoid foraging after dusk and many mammals hibernate over winter. Energy stores are built up during times of food abundance when it is easy to acquire calories. In the natural world and in human history, gluts of food are common. In temperate environments, food is plentiful in autumn, when hibernating animals quickly gain weight. Many tropical environments have highly seasonal rainfall which results in overabundance of food at some times and severe shortage in others.

Models based on the idea of a target level of reserves have been developed that incorporate the role of occasional gluts of food, rather than just the risk of food shortage (McNamara et al. 2015). If energy reserves can be built up cheaply when food is abundant, humans may have evolved two set-points: one for normal conditions and one in glut conditions. The latter is much higher despite some health costs because it is not expected to last and the other costs are avoided while reserves are high. In modern constant glut conditions, people are always at the upper set-point. This model predicts that the mortality rate from obesity in constant glut conditions should be roughly equal to the mortality from predation (or disease) in our ancestors.

Another model incorporates information in that the long-term food availability is not known perfectly and is learnt from experiences (Higginson and McNamara 2016). The target level is therefore dependent on what is learnt, and if the system expects food shortages to be common then more fat should be stored. This model led to the suggestion that severe diets may “teach” the system that food shortages are common, leading to yo-yo dieting and long-term weight gain as often observed (Dankel et al. 2014).

How optimal fat storage might be predicted to respond to increase in the availability of food depends on the costs of gathering extra calories (Houston and McNamara 1989). If the availability of food increases then whether this leads to an increase in body reserves depends on the statistical characteristics of the food supply the animal is adapted to. If the food supply is not clumped over time and space then increasing food availability decreases fat levels due to the reduced need for insurance against a run of bad luck.

In contrast, if the food supply is clumped such that the risk of starvation is negligible most of the time (e.g., occasional famines), and between famines the animal has time to replenish fat stores, increasing food availability increases fat storage. This is because the gain rate only affects the probability of predation because the animal is highly likely to reach any target before the next famine so only has to ensure it gets there while minimizing the costs of reaching exposure to predators. Increased food availability means it is “cheaper” to gain weight and so it is optimal to gain more weight.

Experiments involving supplementing food supplies usually result in animals gaining weight (Boutin 1990), suggesting that animals perceive supplementary food as cheap to acquire rather than indicating reduced likelihood of food shortage in the future. If humans perceive the widespread availability of food in the modern world as cheap to consume but not reassuring in terms of the future, then we would expect widespread obesity. Understanding the control of body reserves sufficiently to prevent obesity may require incorporating the insights from all the current models.

Conclusion

Evolutionary models of body reserves have the ability to identify the mechanisms that control eating and energy expenditure, and therefore identify how they might have gone awry in obese people.

Thermoregulation

Definition

Thermoregulation is the process through which the central nervous system employs information

from temperature and other sensors to adjust the activity of tissues that are specifically responsible for heat production and those that regulate heat loss from the body.

Introduction

In mammals, the temperature of the body core (T_{core}) is a critical physiological variable that is tightly regulated to optimize cellular function, in particular enzyme kinetics and membrane ion flows. T_{core} represents the heat content of the body, which is the balance point between the heat produced by the metabolic processes of the body and the heat lost from the body to the ambient environment. The primary basis for heat production is the breakdown of ATP, the energy molecule which most cells employ to accomplish their basic and tissue-specific functions. The conversion of ATP to ADP to perform work is an inefficient process in which approximately 50% of the triphosphate bond energy in ATP is lost as heat. Thus, basal heat production (i.e., basal metabolic rate) arises from all the fundamental, ATPase-facilitated cellular processes from molecular transport and the maintenance of ion gradients across membranes, to protein synthesis and cell division. Added to basal metabolic heat production is the intermittent generation of heat from the wide variety of tissue-specific functions, most significantly the postural and locomotor activity of skeletal muscles and the acquisition of fuel and elimination of waste in the gastrointestinal organs and the liver. Heat is lost by conduction and radiation from the body surface (i.e., the skin, a.k.a. the body shell) to the molecules of the ambient environment (e.g., air or water) whenever the temperature of the immediate environment is lower than that of the body surface, and conversely, the body will gain heat (negative heat loss) when exposed to an environment that is warmer than the body surface, or to a source of radiant energy (e.g., infrared heat lamp) that is absorbed by the body. The amount of heat available to be lost is strongly dependent on the level of blood flow in skin blood vessels.

Fundamental Thermoregulatory Circuits

In mammals, T_{core} is regulated by the central nervous system through its neural control of a variety of behaviors and physiological processes that influence the amount of heat lost to the environment or that produce heat (Morrison and Nakamura 2019; Romanovsky 2014; Tan and Knight 2018). The primary goal of the dedicated thermoregulatory circuits in the brain is to maintain a stable T_{core} that is optimal for the function of the cells in the brain and the body tissues. These circuits are also responsible for adjusting T_{core} to new levels to optimize organismal performance in response to various challenges or during behavioral states. For example, T_{core} is increased to improve immune responses to fight infection, and T_{core} is reduced to lower cellular metabolism when food intake is eliminated during sleep or fasting. The basic neural circuits for thermoregulation contain (1) sensory or afferent components consisting of thermoreceptors; (2) neural integration networks in which thermal signals are integrated with a wide variety of inputs related to metabolic and osmotic status and behavioral state; and (3) efferent or motor components which are neural pathways that respond to the outputs of the integration network to control thermoregulatory behaviors and to determine the levels of activity on the nerves controlling the tissues (thermoeffectors) responsible for heat loss and heat production.

Effector Mechanisms for Body Temperature Regulation

The repertoire of thermoregulatory behaviors is extensive, from simple curling up or limb extension body positions to complex clothing and home heating and air conditioning systems. In general, the goal of thermoregulatory behaviors is an adjustment in the level of heat loss to reduce the “thermal discomfort” of being in an ambient temperature environment that is outside the thermoneutral zone. Additionally, thermoregulatory behaviors such as warm-seeking and cold-seeking

behaviors can make a significant contribution to state-dependent changes in T_{core} . For instance, in immune system responses, movement to a warm environment contributes to the increased T_{core} during fever, and the preference for a cold environment helps reduce T_{core} during septic shock.

The principal tissues for thermoregulatory heat production (thermogenesis) are brown adipose tissue (BAT) (Cannon and Nedergaard 2004) and skeletal muscle, through shivering (Nakamura and Morrison 2011). In BAT, an uncoupling protein in the mitochondrial membrane shunts the proton gradient energy from ATP production into heat, which is carried away from the BAT depots via the circulation. Thermogenesis in BAT is controlled by the sympathetic nerves that innervate this adipose tissue. The increased tension and short, rapid contractions of skeletal muscle during shivering consume significant amounts of ATP and thus result in increased heat production. Shivering thermogenesis is driven by the same alpha motoneuron innervation of skeletal muscle that controls normal postural and locomotor activity.

The principal mechanism for influencing the loss of metabolic heat from the body is the regulation of cutaneous blood flow: increasing skin blood flow by dilating the skin blood vessels increases heat loss (if the ambient temperature is less than T_{core}), while constricting cutaneous blood vessels reduces skin blood flow and conserves metabolic heat in the body core. Heat transfer to the environment occurs from the skin in humans, from the ears of rabbits and elephants, and from the tails of rats and mice. Skin blood flow is controlled by the cutaneous vasoconstrictor sympathetic nerves that innervate the smooth muscle of blood vessels (McAllen and McKinley 2018). There is an additional sympathetic vasodilator innervation of skin blood vessels in humans. Heat loss can be augmented by evaporating water from body surfaces, such as sweating in humans, panting in dogs, and saliva spreading in rodents. This is the only effective mechanism for heat loss in an environment that is warmer than T_{core} . Heat loss can be reduced by piloerection, in which the erect hairs on the body surface retain a thin layer of warm air that provides an insulating barrier

between the skin and the colder ambient air. Sweat glands and hair follicles receive sympathetic innervations that are activated in heat defense and cold defense responses, respectively.

Thermosensory Pathways Influence the Nerve Activity Controlling Thermoeffectors

Thermoreceptors in the skin provide the brain with “advanced warning” of an environmental temperature challenge to T_{core} . Cutaneous thermoreceptors are specialized sensory nerve endings in the skin whose cell membranes contain ion channels that respond to non-noxious levels of cooling or warming of the skin. Thus, cold thermoreceptors become active when exposed to cool ambient temperatures, causing increased activity on cold sensory nerves that synapse in the dorsal horn of the spinal cord. Warm thermoreceptors are activated when the skin is exposed to warm environment and lead to increased activity on warm sensory nerves that also enter the spinal cord. Cold and warm sensory nerves from the head synapse in the trigeminal nucleus in the brain stem. The temperature within the body core is sensed by cold and warm thermoreceptors in many tissues within the body and also by uniquely temperature-sensitive neurons in localized regions of the brain.

Thermosensory signals are transmitted from the spinal cord to an intermediate brain stem site in the parabrachial nucleus and then to the thermoregulatory integration center in the preoptic area of the hypothalamus (Nakamura and Morrison 2008). The outputs of the preoptic area influence the motor or efferent pathways controlling the activity of the thermoeffector tissues described above. Spinal and trigeminal thermal information is also conveyed to the thalamus and then to the cerebral cortex for the conscious perception and localization of thermal stimuli. The neurons in the preoptic area provide a basis for the integration of thermal afferent signals with those related to behavioral states (e.g., sleep, during which there is a fall in T_{core}), metabolic status (e.g., fasting or hypoglycemia, which results in a fall in T_{core} to lower the metabolic demand for fuel), immune responses (e.g., fever, in which T_{core} is elevated to improve host defense

responses), and cardiovascular status (e.g., hemorrhage, which elicits a fall in T_{core} to reduce metabolism in the face of a reduced tissue delivery of energy substrates).

The integrated outputs of the preoptic area provide excitatory, primarily glutamatergic, and inhibitory, primarily GABAergic, influences on hypothalamic (e.g., dorsomedial hypothalamus) and brain stem (e.g., raphe pallidus) neurons whose activity is critical for activating the sympathetic and somatomotor nerves that determine the level of thermoeffector activity. In particular, the raphe pallidus contains both sympathetic and somatomotor premotor neurons that project to the spinal cord to provide a critical excitatory input to the sympathetic preganglionic neurons and alpha motoneurons, respectively. To complete the thermoregulatory reflex circuits, various populations of sympathetic preganglionic neurons drive the different sympathetic nerves to BAT, cutaneous blood vessels, sweat glands, and hair follicles, while various populations of alpha motoneurons drive shivering in different groups of skeletal muscles.

During cold defense (or fever), heat conservation behaviors are engaged, heat loss is reduced by increasing cutaneous vasoconstriction and piloerection and inhibiting sweating, and BAT and shivering thermogenesis are increased. During heat defense, heat loss behaviors are initiated, sympathetic cutaneous vasoconstriction and piloerection are inhibited and sweating is activated to increase heat loss, and BAT and shivering are inhibited to reduce thermogenesis. Increases in brain temperature lead to fatigue as a mechanism to reduce metabolic heat production from exercising muscle. The significant water and electrolyte loss during heat defense in a warm environment presents increased cardiovascular and osmotic challenges, stimulating thirst and requiring substantial fluid consumption to prevent cardiovascular collapse and death. In combination with certain tissue adaptations, the thermoregulatory circuits in the brains of hibernating and torpid mammals enable them to markedly lower their T_{core} to reduce cellular metabolism during extended periods of reduced food availability.

Areas for Future Research

Although many aspects of the functional organization of the dedicated thermoregulatory circuits in the central nervous system have been discovered, considerable additional research is needed to provide a more detailed understanding of these circuits and how their pharmacology might be harnessed to combat disease. What are the neural mechanisms responsible for the changes in Tcore that accompany different behavioral states such as sleep (Chung et al. 2017; Kroeger et al. 2018) or hibernation (Tupone et al. 2017)? How do nonthermal inputs impinge on the basic thermoregulatory network to influence Tcore (Madden and Morrison 2016)? How does traumatic brain injury affect the thermoregulatory network to produce neurogenic fever? How can our understanding of these alterations in the central thermoregulatory circuits be recruited to discover new therapies, such as deep hypothermia, or new pharmacological approaches to alter Tcore and metabolism to combat disease and improve recovery from injury?

Conclusion

The principal thermoregulatory effectors are the cutaneous blood vessels for control of heat loss, the BAT, and skeletal muscle for thermogenesis and sweating for evaporative heat loss. The activation of these effectors is regulated by parallel but distinct, effector-specific, core efferent pathways within the central nervous system that are strongly influenced by shared cutaneous thermal afferent signals. Thermal sensory information is integrated with a variety of other metabolic and behavioral signals in the preoptic hypothalamus to generate a constellation of output signals that optimize the use of available energy and fuel supplies to maintain or adjust body temperature to cope with environmental challenges or the requirements of various behaviors.

Bone Lissoir

Nicholas Primavera
SUNY New Paltz, New Paltz, NY, USA

Synonyms

[Smoother](#); [Similar tools are also called Slickers and Burnishers in modern leather-work](#)

Definition

A leather-working tool constructed out of an animal bone.

Introduction

The bone lissoir was a tool that was speculated to be used by Neanderthals. The primary function of this tool was increasing the pliability and water resistance of hides or skins.

The Bone Lissoir and Its Importance

The bone lissoir was first discovered in France and is considered to be one of the first specialized tools used by Neanderthals. It is a simple tool consisting of a curved bone, such as a rib, that has one end shaped to a rounded, curved end. The choice of a bone for this tool was ideal, primarily due to the fact that bones are somewhat flexible and would not break as easily as other materials. The use of wood would most likely be less than ideal, as chances are it would snap easier than bone. Furthermore, the use of stone tools such as handaxes would certainly rip or damage the hide, thus

rendering it useless. However, bone blends the strength of stone with some of the flexibility of wood, providing the correct amount of pressure needed to work the pelt. “Neanderthals sometimes made scrapers, notched tools and even handaxes from bone. They also used bone as hammers to resharpen their stone tools, but here we have an example of Neanderthals taking advantage of the pliability and flexibility of bone to shape it in new ways to do things stone could not do” (McPherron 2013). The deliberate shaping of the smooth, curved end provides evidence for intentional specialization of the tool, as the ribs of deer or reindeer do not have a smoothed end naturally. Furthermore, abrasions along the sides of the smoothed end further support the idea that this tool was modified in some way. It is believed that the tool was used to apply pressure with the curved edge on animal hides and pelts in an upward fashion. Doing so stretches the hide as well as increasing its luster, water resistance, and durability. Modern leatherworkers use a similar tool today in order to make hard leather be shaped into various clothing items and accessories. Discovered bone lissoirs have been dated to approximately 50,000 years ago, which, according to current theoretical models, do not line up with Neanderthals and modern humans in Europe in general. According to Shannon McPherron, senior archaeologist in the Department of Human Evolution at the Max Planck Institute for Evolutionary Anthropology in Leipzig, “The dates make the bone tool finds the earliest known of their type associated with Neanderthals. Usually, such tools have been identified with modern humans who came upon the scene at a later time, but the dating and their location within a context of MTA stone tools, which are usually associated with Neanderthals, suggest that they were created by Neanderthals, not modern humans” (McPherron 2013).

Conclusion

The bone lissoir was perhaps the first specialized tool used by Neanderthals. Even though it may have been constructed over 50,000 years ago, its design has transcended time, and similar methods

are used today in order to work various leathers and other materials. Its importance with regard to evolutionary studies is also quite profound. Its dating has suggested that Neanderthals were the ones that first invented the bone lissoir, not modern humans. Although this certainly does not prove anything, it does offer the opportunity for further research.

Bonobo Sexuality

Kara K. Walker and Emily E. B. Boehm
Evolutionary Anthropology, Duke University,
Durham, NC, USA

Bonobos (*Pan paniscus*) stand out among primates for the frequency and flexibility with which they engage in sexual behavior. To a far greater degree than chimpanzees, their congeners, bonobos mediate their social relationships using sex, frequently substituting sociosexual behaviors for aggression. The relative prevalence of sex and rarity of both intra- and inter-group aggression is the defining feature of bonobo sexuality.

Bonobos are highly social and cognitively complex animals, and as such, their sexuality can only be understood from a social perspective. Bonobos live in large, permanent social groups, though the entire group is rarely together due to the fission-fusion structure of their communities: subgroups for traveling and foraging form and split on a daily basis (White 1988). Bonobos are male philopatric and females leave their natal community shortly after attaining sexual maturity (Furuichi 1989). Therefore, resident adult females tend to be unrelated. Bonobos are unusual among anthropoid primates in that they are female dominant. The absence of kin typically limits the

formation of bonds between members of the dispersing sex, but female bonobos maintain their dominance over males, in spite of their smaller body size, through the use of strategic alliances cultivated through female-female affiliation (White and Wood 2007). Bonobo males remain strongly bonded to their mothers throughout their lives, and these pairs frequently travel together (Furuichi 1989; Surbeck et al. 2011). Mothers support their sons in aggressive encounters, and, as a result, sons of high-ranking mothers tend to become the highest-ranking males. Higher-ranking males, in turn, tend to produce more offspring (Surbeck et al. 2011).

Like other primates, bonobos engage in sexual behavior for conceptive purposes, and female bonobos give birth every 4–6 years (Kano 1992; de Waal 1997). Mating is promiscuous, paternity certainty is low, and there is no evidence of direct paternal care or male infanticide. However, much of the sexual behavior in bonobos is sociosexual in nature and is used to reduce tension, indicate social status, and maintain relationships both within and between social groups (de Waal 1997). Sociosexual behavior is most simply defined as sexual behavior that does not have a conceptive benefit for either partner (Wrangham 1993). Bonobos use various copulatory positions, including ventro-ventral (Kuroda 1980), which is used in almost one out of every three copulations in the wild (Kano 1992). This position is rarely, if ever, employed by chimpanzees. Female bonobos seem to prefer the ventro-ventral position to the more common primate position of dorso-ventral (Kano 1992). The vulva and the clitoris have a frontal orientation in bonobos, and the clitoris is more prominent than in the chimpanzee (Savage-Rumbaugh and Wilkerson 1978), suggesting that the female genitalia are adapted for ventro-ventral contact. Non-conceptive sex is practiced among partners of all ages and both sexes, and infants begin participating at a young age (Kano 1992). Genito-genital (G-G) rubbing commonly occurs between females in the ventro-ventral position. Fellatio, mouth-to-mouth kissing, and hand-to-genital contact also sometimes occur (de Waal 1987). Sociosexual behavior is observed at relatively high frequencies in captive populations

where food provisioning and small enclosures elevate group tension (Savage-Rumbaugh and Wilkerson 1978; de Waal 1987) but is also common in wild populations (e.g., Kuroda 1984). Sociosexual encounters are most frequent in feeding contexts, such as arrival at a large fruiting tree, or in other situations where individuals may need to diffuse tension, such as following an aggressive encounter.

A key tenet of the hypersexuality seen in bonobos is extended female sexual receptivity. Female chimpanzees are only sexually receptive during the tumescent phase of their ovarian cycle which typically lasts for 12–13 days in a 35-day cycle. After conception, females may experience a small number of sexual swellings, though some may continue to cycle long into gestation. After birth, females experience a period of lactational amenorrhea that lasts an average of 3.5 years. Once cycling resumes following lactational amenorrhea, a female may only experience a handful of cycles before conceiving again (Tutin 1979; Wallis 1997; Deschner et al. 2003; Thompson 2013). A female chimpanzee, therefore, may only be sexually receptive for <4% of her life. In contrast, bonobo females may be sexually receptive for up to 48% of their lives (Wrangham 1993). Sexual cycles in bonobos last approximately 42 days and with a tumescent period of an average of 10–14 days, though this is highly variable and can exceed 30 days (Douglas et al. 2016). After the onset of sexual cycles at around 7 years (~2 years earlier than in chimpanzees), females are maximally swollen nearly continuously until shortly before their first birth (Kano 1989). Bonobos experience sexual swellings later into pregnancy than do chimpanzees and, after birth, resume cycling much earlier, sometimes in under a year (Kano 1989). Despite their increased receptivity, bonobos mate at a lower rate than chimpanzees (Furuichi 1987); each encounter lasts on average only ~13 s. Bonobo females tend to concentrate their matings when their swelling is at a maximum firmness, rather than maximal size, a period that better corresponds to the duration of maximal swelling in chimpanzees (Furuichi 1987). Bonobos also have increased opportunity to mate as a

result of their grouping patterns. Females spend close to 100% of their time in proximity to at least one male (White 1988; Kano 1992), while chimpanzee females range alone up to 40% of the time (Wrangham and Smuts 1979; Murray et al. 2007).

Intrasexual competition limits the mating success of both males and females, while intersexual competition is rare in bonobos (Hohmann and Fruth 2003; Surbeck et al. 2011). Indeed, male aggression against females is near its lowest when females are maximally tumescent. Sexual coercion may be ineffective in bonobos because males fear retaliation from both females and males. This suggests that the benefits of affiliative relationships between males and females may outweigh any reproductive advantage males receive through being aggressive to females (Hohmann and Fruth 2003). Moreover, because swellings are extremely unreliable as an indicator of ovulation (ovulation can even occur outside the maximally swollen period) (Reichert et al. 2002; Douglas et al. 2016), bonobo males may need to maintain relationships with females over the entire cycle, making mate guarding an inefficient and likely ineffective strategy (Hohmann and Fruth 2003).

The stark differences between chimpanzee and bonobo sexuality are hypothesized to originate from differences in feeding ecology that affect sociality (Wrangham 1993; Hare et al. 2012). Evolutionarily, bonobos are thought to have had increased access to large patches of high-quality, terrestrial foods that can be consumed during travel, which may have limited within-group feeding competition (Wrangham 1993). Reduced competition allows females to associate for longer periods and more frequently in mixed-sex parties outside of her ovulatory period and increases opportunity for female-female coalitions (Hare and Wrangham 2012). For males, continual access to females and the weak connection between ovulation and swelling reduced the effectiveness of sexual coercion as a reproductive strategy (Hohmann and Fruth 2003). Support for ecological differences in the current chimpanzee and bonobo ranges is mixed (Hohmann et al. 2010), leaving this question open to debate. However, ongoing research into cognitive differences between the two species supports the hypothesis that chimpanzees and bonobos

evolved under divergent environmental conditions that have favored higher levels of cooperation, sharing, and even empathy in bonobos (Hare et al. 2012).

Definition

Boredom is an affective state, typically unpleasant and characterized by scarce stimulation and concentration in the current situation or activity that may have evolved to motivate bored individuals to pursue more desirable states of being.

Introduction

Boredom is an affective state that involves low arousal, disinterest in the present setting, and feelings of dissatisfaction. Bored individuals may also feel that time passes more slowly (Fisher 1993). Physical signs of boredom in an individual typically include leaning the head back, yawning, and decreased motor activity (Park et al. 2019). Most people typically perceive the experience of boredom as displeasurable and would prefer to avoid it if possible. For instance, Wilson et al. (2014) found through 11 studies that many people preferred receiving electric shocks rather than being left alone with nothing to do. Yet, the ubiquity of boredom in the human experience suggests that boredom may be a well-designed psychological mechanism that conferred an evolutionary advantage in host organisms – that is, our evolutionary ancestors who were prone to boredom were better off than those who were not. An evolutionary approach to boredom suggests that more attention should be paid toward understanding the role of this important emotional state in the lives of human beings.

Reasons for Boredom

Research has identified several causes of boredom. From an individual difference perspective, some people may be more prone to boredom than others. For example, individuals who score high on extraversion require more stimulation to remain aroused and engaged in tasks and are more likely than introverts to be bored when presented with monotonous tasks (Fisher 1993). Researchers have also sought to establish boredom proneness as a stable trait using assessments such as the Boredom Proneness Scale or the Boredom Susceptibility Subscale (Vodanovich 2003).

Boredom may also be caused by situational factors, such as when one has nothing to do and is inadequately stimulated (Fisher 1993). Importantly, the opposite of boredom is not necessarily a state of busyness. The perception of surfeit, which arises when an activity is deemed to be in excess to the point that it is no longer desirable, can also prompt feelings of boredom, especially when combined with task monotony, predictability, and feelings of confinement (Toohey 2011). In such cases, boredom can be triggered when the task environment lacks novelty and variety in stimulation. Similarly, the availability and quality of social interaction in the task environment may also contribute to feelings of boredom. For example, a social environment comprising slow or unemotional exchanges between coworkers may prompt the onset of boredom (Fisher 1993).

Behavioral constraints in the task context may also produce boredom (Fisher 1993). Rules and task regimentation limit the variety of stimulation available in the work environment and also infringe on people's need for autonomy by restricting their choices in work activities and behaviors. Such restrictions inadvertently induce some level of psychological reactance, which may manifest as a need to reassert control over choice freedom and a greater liking for prohibited activities simply because they are forbidden (Fisher 1993). In this manner, present activities decline in attractiveness and become boring by comparison.

Boredom as an Evolutionary Adaptation

While the experience of boredom is usually accompanied by a lack of motivation and resentment in the *present* activity setting, it might also adaptively predispose a person to pursue *future*, more viable alternative activities and goals. Bored individuals often report restlessness and a desire to be engaged in something else instead (Bench and Lench 2013). The drive induced by boredom, which motivates individuals to seek alternative activities and more desirable circumstances, might have been adaptive for early humans adjusting and living in ancient environments. In particular, the capacity to feel bored and to respond in ways aimed at reducing boredom

may have helped ancestral humans avoid stagnation, learn new skills, and devise creative solutions to overcome survival and reproductive challenges in ancient environments. The proclivity to feel dissatisfied with the current situation and improve upon it through innovation, such as the development of new technology or new ways to exploit the environment, may have also given ancestral humans an edge over conspecific rivals in competition for scarce resources. Consistent with this view, researchers have found that boredom triggers thought processes and behaviors that are conducive to creativity, in particular by motivating individuals to engage in divergent thinking and exploratory behaviors (Park et al. 2019).

Boredom may also play a signaling role in the regulation of mastery and play, thus keeping individuals engaged so long as learning and play activities return stimulating, interesting, or rewarding outcomes. The boredom experienced by an individual during an activity may reflect the activity's diminishing utility and, hence, declining satisfaction for the individual (Eastwood et al. 2012). As such, boredom can be adaptive for learning because it reduces interest in the current, unsatisfying activity and motivates the search for new activities or surroundings that promise greater stimulation (Bench and Lench 2013). Hence, boredom facilitates a reduction in effort investment in unstimulating activities and drives the pursuit of alternative goals, thereby enabling humans to engage in social, cognitive, and emotional experiences that would have otherwise been missed (Bench and Lench 2013).

The experience of boredom may also be adaptive in mating contexts. Some preliminary evidence supporting this idea comes from studies that have examined sex differences in susceptibility to boredom and found that males are more prone to boredom than females (Sundberg et al. 1991). In mating situations where males are required to invest significant effort in self-presentation and intrasexual competition for the attention of and access to potential mates, the experience of boredom may help curb overexpenditure of mating effort, especially when sexual attention is either unreciprocated or already acquired. Thus, boredom may help males

optimize their investments in mating effort and prompt them to move on to the next candidate when it is more reproductively viable to do so. In so doing, males can avoid fixation on mates who are either unresponsive or who have already been potentially fertilized and continue to attract as many mates as possible.

Evolutionary Mismatch Between Modern Environments and Innate Capacities for Boredom

A state of boredom readies the individual for the pursuit of alternative experiences that could be beneficial to learning and development (Bench and Lench 2013). However, modern technologies, in particular handheld mobile devices, afford people a quick and addictive solution to deal with “dead time,” or small pockets of time where people are unfocused on any specific activity (Røpke and Christensen 2012), by providing near-reflexive levels of access to social media as well as stimulation via mobile gaming applications (Lord et al. 2015).

This scenario illustrates an evolutionary mismatch between humans’ innate capacity to experience boredom and features of the modern environment that are rife with stimulation designed to eliminate or dull the experience of boredom (Li et al. 2018). From a mismatch perspective, such novel forms of stimulation hijack our capacity for boredom, which should otherwise usefully impel humans to engage in creative thinking processes, seek new forms of stimulation, and change the status quo, thus causing people to miss out on the adaptive benefits of feeling bored. These periods of dead time, which are commonly experienced during daily commutes or service waiting times, are antecedents of boredom that may have functioned to motivate the drive for creativity and innovation. Thus, an evolutionary perspective suggests caution when choosing to occupy dead time with filler activities afforded by modern mobile technologies: while this might stave off the aversive feeling of boredom in the short run, it can also starve individuals of the impetus needed to become more creative and explore activities beneficial to survival and development.

Conclusion

Boredom might seem like an inconsequential or troublesome phenomenon at first glance. However, an evolutionary perspective suggests that boredom may serve important adaptive functions, in particular the search for more desirable or rewarding activities and circumstances (Bench and Lench 2013; Fisher 1993). Thus, the antecedents and consequences of boredom as well as how boredom unfolds over time deserve further research attention. If the mechanisms underlying boredom are better understood, individuals and organizations can go beyond seeking how to eliminate boredom and instead design activities and environments that can harness the benefits of boredom and optimize human functioning.

Bottle Feeding

Gordon G. Gallup¹ and Jennifer A. Stolz²

¹State University of New York at Albany, Albany, NY, USA

²Department of Psychology, University of Waterloo, Waterloo, ON, Canada

Synonyms

Dry nurse; Formula feeding

Definition

Feeding a baby with milk (or formula) from a bottle instead of from the mother's breast.

Bottle Feeding Is an Evolutionary Mismatch

Introduction

Until recently in human evolutionary history, there were no alternatives to vaginal deliveries or breastfeeding, and nursing used to last 3–4 years (Tönz 2002). Nowadays fewer than 40% of infants worldwide are breastfed for the first 6 months of life, and among high-income families, it drops to a meager 18% (see Gallup et al. 2016 for details). Bottle feeding is an evolutionary

mismatch because it puts the mother and baby out of phase with the defining feature of mammalian evolutionary history.

Formula Is a Poor Substitute for Breastmilk, and Bottle Feeding also Puts Mothers at Risk

Because of nutritional deficiencies in formula (e.g., the absence of long chain polyunsaturated fatty acids necessary for healthy brain growth and development, colostrum which contains antibodies from the mother, and bacteria on the mother's breasts that cultivates and jump starts the baby's intestinal flora and immune system), bottle-fed children can be cognitively challenged, immunocompromised, and prone to suffer from asthma. To make matters worse, mothers who bottle feed are more likely to become overweight (Chapman 2009); more prone to develop breast cancer (Stuebe et al. 2009a), ovarian cancer (Su et al. 2013), rheumatoid arthritis (Jacobsson et al. 2003), type 2 diabetes (Steube et al. 2005), myocardial infarct (Steube et al. 2009b); and have an elevated risk of experiencing postpartum depression (Gallup et al. 2010).

Bottle Feeding Simulates Child Loss

Until recently, the decision not to breast feed would have been tantamount to committing infanticide. More often, it was the case that the failure to breast feed was occasioned by stillbirth or other forms of neonatal fatality, and therefore at the level of the mother's basic biology bottle feeding simulates child loss (Gallup et al. 2010). The death of a child is a powerful trigger for depression, and bottle feeding increases the risk of postpartum depression by as much as 50%. Consistent with this analysis, depressive episodes can accompany weaning as well because it also simulates child loss. To complicate matters further, nowadays some women with postpartum depression are treated with antidepressants and are advised to stop breastfeeding because of problems posed by the medication getting into their breastmilk. Mothers who bottle feed their babies also report wanting to hold their babies more, which may be reminiscent of nonhuman primates where mothers often persist in clinging to and carrying their dead babies for prolonged periods of time. Hospital

practices of separating babies from their mothers for the first few days of life and keeping them in nurseries also unwittingly simulate child loss and may increase the risk of postpartum depression.

Bottle Feeding Increases the Likelihood of Autism in Your Next Child

Most people also don't realize that bottle feeding puts the evolved birth spacing mechanisms on hold. Pregnancy and breastfeeding are nutritionally very expensive, and reimpregnation shortly after birth could adversely affect the quality of milk for the baby while also compromising the nutritional status of the prenatal environment for the fetus. As an evolved solution to this problem, breastfeeding triggers hormonal changes that postpone the resumption of the menstrual cycle (lactational amenorrhea) and inhibit the release of eggs (lactational anovulation). As a result, mothers who opt to bottle feed are more likely to get pregnant again sooner after the birth of a child (Gallup und Hobbs 2011). Research shows that the risk of autism is three times higher among children who are conceived within a year of their next oldest sibling (Cheslack-Postava et al. 2011), and this may be due to incomplete recovery of the prenatal environment. The high degree of concordance in autism, not only among identical twins, but among fraternal twins as well, is consistent with this prenatal environment hypothesis (Ronald et al. 2006). Closely spaced pregnancies also put babies at an elevated risk of sibling rivalry, being born prematurely, and dying prior to 5 years of age (Rutstein 2008).

Bottle Feeding and Caesarean Sections

Just like bottle feeding, caesarean sections were not an option during our evolutionary history. Indeed, C-sections are also an obstacle to breast feeding because they often lead to delayed contact between the baby and the mother, side effects of drugs used during C-section deliveries that leave babies groggy and less responsive, and diminished postpartum levels of oxytocin and prolactin that would otherwise promote maternal bonding (for a review see Gallup et al. 2016). Being overweight is an artifact of modern agriculture, and it is another impediment to breast feeding because

of difficulties overweight mothers experience when attempting to hold the infant and embarrassment about breast feeding in public. To complicate matters further, obese women are also more likely to have C-sections (Sebrie et al. 2001).

In terms of evolutionary mismatches, it is also important to note that babies born by C-section are immunocompromised because they do not ingest some of the bacteria in the mother's vagina as would usually occur during a normal vaginal delivery. As a consequence C-section babies are at an elevated risk of developing asthma.

Putting Evolved Mechanisms Back on Track

Breastfeed if you can, but if you can't, use condoms after your baby is born in order to prevent an untimely pregnancy. If you have to work, try expressing breastmilk and have a caretaker bottle feed the breastmilk to your baby. To overcome problems with expressing milk try recreating the context in which breastfeeding occurs, such as looking at a picture of the baby when you express milk. An even better strategy would be to position a camera over your shoulder to make a video clip of your baby breastfeeding that includes sounds the baby makes while suckling to capture what you experience when you breastfeed. Then express milk while watching the video and smelling the baby's clothes. Indeed, it would be interesting to compare both the quantity and the quality of milk expressed by women under these enhanced conditions, relative to an environment not augmented with personal reminders of the infant.

Conclusion

Bottle-feeding presents serious consequences for both infant and mother. Suggestions to overcome some of these are made.

Bounded Rationality

Ozan Isler

Centre for Behavioural Economics, Society and Technology, School of Economics and Finance, Queensland University of Technology, Brisbane, QLD, Australia

Synonyms

Ecological rationality

Definition

Theory of imperfectly rational decision-making processes under cognitive resource limitations.

Introduction

The theory of bounded rationality, proposed by Herbert A. Simon (1957), is a progenitor of the behavioral turn in modern economics. It provided a viable and realistic alternative to the idea of *homo economicus* and the optimality criterion of utility maximization. Simon called his alternative criterion *satisficing*, the decision-making process whereby a course of action is chosen if it yields at least as much value as an ecologically adaptive *aspiration level* (Simon 1955). As distinct from theories that assume perfect rationality and optimal behavior, the theory of bounded rationality takes into account human cognitive limitations, decision processes, and environmental adaptations. Summarizing bounded rationality, Simon wrote that “Human rational behavior [...] is shaped by a scissors

whose two blades are the structure of task environments and the computational capabilities of the actor” (Simon 1990).

The Theory of Bounded Rationality

Simon criticized the assumption of perfect rationality in economics by emphasizing natural biological limits of human cognitive processes (Simon 1955). While standard economic theory of decision-making considers environmental resource constraints (e.g., income and market prices), the theory of bounded rationality additionally takes into account cognitive constraints and adaptations. Cognitive constraints include the limited capacity of our minds in processing information about the outside environment, for example, in forming limited representations of the decision problems due to short-term memory constraints (Simon 1990). Cognitive adaptations include decision-making strategies such as rules of thumb or heuristics that allow problem simplification (Simon 1979).

Satisficing is the decision criterion Simon proposed in his theory of bounded rationality as replacement for the criterion of utility maximization (Simon 1986). For a boundedly rational agent, decision-making processes involve exploration of uncertain environments for attaining goals (e.g., finding food for survival) using adaptive cognitive algorithms (e.g., heuristics). The search process comes to a halt, or at least it is momentarily paused, when a “good enough” solution is found. Simon shows how satisficing can allow survival in uncertain (e.g., basic animal behavior foraging) and complex worlds (e.g., a chess game) without utility maximization (Simon 1956).

Another important theoretical component of Simon’s theory of bounded rationality is the idea of *aspiration level*, which determines the threshold of value for determining whether a solution is satisfactory or not (Simon 1955). Simon suggests that boundedly rational decisions are adapted to the environment in at least two ways. First, the aspiration level depends on the environment: “A vague principle would be that as the

individual, in his exploration of alternatives, finds it *easy* to discover satisfactory alternatives, his aspiration level rises” (Simon 1955, p. 111). Second, boundedly rational decision-making processes benefit from shortcuts such as heuristics – mental shortcuts that work well in certain environments and that save cognitive effort (Simon 1990).

Influence

The theory of bounded rationality has been very influential in behavioral sciences, and it has paved the way to new research fields such as behavioral economics. However, different interpretations of the theory – in particular, whether heuristics tend to be beneficial or not – resulted in two distinct but intimately related behavioral research agendas. On the one hand, Daniel Kahneman and Amos Tversky’s “biases and heuristics” approach focused on uncovering cognitive biases that result in poor decisions (Kahneman 2003). On the other hand, Gerd Gigerenzer’s “fast and frugal heuristics” approach emphasized how – despite cognitive limitations – simple rules are often reliably beneficial because they are ecologically rational (Gigerenzer and Goldstein 1996). Even though Simon’s own views were perhaps better aligned with the latter interpretation of heuristics, the “biases and heuristics” interpretation became prevalent in behavioral economics and resulted in an emphasis on nudges or external tools for improving decision-making (Thaler and Sunstein 2008). These different traditions for interpreting the role of heuristics and biases continue to shape behavioral research, such as dual-process perspectives on social and moral decisions (Isler and Yilmaz 2019).

Conclusion

The theory of bounded rationality initiated a foundational reconsideration of economic theories of decision-making from the perspective of

evolution and psychology. The effects of Simon's theory on behavioral research are still ongoing.

Bow-Wow

Demetra Themistocleous and Xenia Anastassiou-Hadjicharalambous
University of Nicosia, Nicosia, Cyprus

Synonyms

[Imitation of sound](#); [Onomatopoeia](#); [Origin of language](#)

Definition

The bow-wow theory supports that language emerged through “onomatopoeia” or the imitation of the sounds in the natural world.

Introduction

The early bow-wow theory of language was first introduced by Max Müller, a philologist who was at a later stage criticized about his point of view (Sprinker 1980). Bow-wow theory postulates that the origin of language arose through “onomatopoeia,” which, in simple words, is the imitation of sounds in nature (Moran and Gode 1986). Specifically, the sounds from animals were the most imitated from the environment. On the one hand, Thorndike (1943) was doubtful about the credibility of this theory as the beginning of language. On the other hand, recent studies support that being able to mimic sounds in the natural environment was of paramount importance in the evolution of language (Malle 2002).

A major drawback of this theory is the fact that people use different words to describe the sounds of animals according to their country and more specifically due to their language. For instance, the sound of a pig can be translated differently across the countries. In English a pig makes the sound “oink-oink”; in Russian it makes the sound “hyru-hyru,” while in Chinese it makes the sound “oh-ee-oh-ee.” Therefore, the sound and pronunciation of the words are not similar among the different languages. The hypothesis that language is determined by how a person interprets a sound was rejected, since there are many languages, and nobody can suggest that human vocabulary arose from these sounds (Thorndike 1943).

Conclusion

The overall idea of the bow-wow theory is that the beginning of language can be linked to the era when the progenitors begun to mimic the sounds in their natural environment. The natural world was of paramount importance in the origination of

language since the sounds of animals played a significant role in the invention of the vocabulary used in verbal communication.

However, the theory holds several limitations that many theorists criticized and questioned its credibility. One, the sound and pronunciation of the words are not similar among the different languages. For example, the sound of a specific animal can be translated differently among the people of different countries, yet animals from the same species make the same sound across the world. The other challenge is that there are few onomatopoeic words in the languages worldwide. In case the theory was credible, then it should have plenty of words out from the basic rule of onomatopoeia.

Boys Bully More Than Girls

Synonyms

[Female-female competition](#); [Intrasexual competition](#); [Male-male competition](#)

Definition

Bullying is a form of aggression where a more powerful individual causes significant harm to a less powerful individual to obtain goals including access to sexual opportunities (e.g., dating and mating partners; Volk et al. 2014). Intrasexual competition for access to dating and mating opportunities is known as sexual selection (Geary 1998). As a form of sexual selection, parental investment is the resources (e.g., time, energy) allocated by parents toward offspring (Trivers 1972). Sex differences in the level of parental investment may help to explain why boys bully more than girls.

Introduction

Bullying significantly impacts the lives of many children and adolescents worldwide. Traditionally, bullying has been viewed as a maladaptive behavior; however, there is evidence to suggest that bullying may be part of an evolutionary adaptation designed to obtain at least three benefits: reputation, resources, and reproduction, all of which are likely to aid in maximizing

biological fitness (see Volk et al. 2012). Sex differences in bullying perpetration consistently find that boys are more likely to engage in bullying than girls, particularly as it relates to physical bullying (e.g., hitting, pushing, kicking). This sex difference in bullying may be tied to evolutionary explanations that provide support for a similar sex difference found in the aggression literature (see Archer 2009).

Sex Differences in Bullying

In contemporary society, most violent crimes (e.g., homicide) and virtually all wars have been perpetrated and fought by males (Georgiev et al. 2013). In addition, the propensity for males to be more aggressive than females may have served an adaptive function in the ancestral environment to improve male reproductive success (Georgiev et al. 2013). From an evolutionary perspective, sex differences in aggression have been argued to be a product of sexual selection (Archer 2009). As a subtype of aggression, bullying behavior may have also evolved as a strategy to obtain goals related to mating and reproduction that were adaptive in the ancestral past and are still adaptive today (Volk et al. 2012). Therefore, similar to aggression, sex differences in bullying may also stem from sexual selection as it relates to intrasexual competition.

Considering that males are usually competing for mates and females are selecting mates (Trivers 1972), bullying may be an adaptive, sex-specific strategy particularly for males. The tendency for males to be the more competitive sex might be related to their lower parental investment in offspring (Trivers 1972). Since males spend less time, energy, and resources producing and raising offspring, they are able to get back into the mating pool sooner to compete again for access to the higher investing females (Puts 2010). Furthermore, males have more variability in reproductive success than females (i.e., males have a greater likelihood of producing a large number of offspring or none at all) heightening the level of competition between

males (Ellis et al. 2012). Lower parental investment in offspring combined with a higher variability in reproduction may explain why males are evolutionarily more tolerant toward risk (Volk et al. 2012). As a result, males are more likely to engage in physical bullying than females because their costs are lower (i.e., they are less important for infant survival; Campbell 1999) and their benefits are higher (i.e., the greater variance in reproductive success rewards taking risks to obtain high benefits, whereas playing it safe can result in zero success; Ellis et al. 2012).

While Trivers' (1972) parental investment theory may explain why males are typically the more competitive sex, it may also explain why females tend to avoid engaging in physical bullying. Compared to males, females have higher parental investment making it especially important to survive and stay away from damaging confrontations in order to care for offspring (Campbell 1999). Furthermore, females have less reproductive variability than males due to internal gestation and breastfeeding, which does not allow them to re-enter the mating pool as quickly (Geary 1998) and uses up a significant amount of energy that is necessary to be successful in physical confrontations (Georgiev et al. 2013). Higher parental investment in offspring combined with a lower variability in reproduction may explain why females are evolutionarily less tolerant toward risk (Volk et al. 2012). As a result, females are less likely to engage in physical bullying than males because their costs are higher (i.e., they are more important for infant survival) and their benefits are lower (i.e., less variance in reproductive success as females are limited by periods of gestation; Campbell 1999). Based on these evolutionary costs and benefits, males may have been selected with a disposition to engage in direct conflict, thus more likely to use riskier, physical bullying, while females may have been selected with a disposition to avoid physical danger, thus more likely to use covert, relational bullying (e.g., gossiping, rumor spreading; Archer 2009). However, while males and females may engage in both physical and relational forms of bullying, the tendency for males to perpetrate more physical

bullying than females may also be reflected in their morphology.

Before the use of objects as weapons, humans relied on their bodies to inflict physical damage on rivals (Georgiev et al. 2013). In general, males are taller, heavier, stronger, and more muscular compared to females (Archer 2009). Males also possess specific physical and cognitive characteristics that may signal their dominance and ability to exclude rivals from the mating pool by force (e.g., beards, eyebrow hair, deep voices, superior targeting abilities for weapon use; see Puts 2010). Moreover, males allocate a large amount of energy toward muscular development granting them the strength and speed required to win damaging confrontations, whereas females direct more energy to meet the demands of internal gestation and breastfeeding at the cost of muscular development (Georgiev et al. 2013). These data suggest that males' anatomy may have been selected to engage in physical bullying in order to compete successfully for access to mates.

In summary, differences in parental investment as a function of contrasting reproductive strategies and physical characteristics may provide an answer as to why males are more likely than females to engage in bullying, particularly physical bullying. Using an evolutionary approach to understand sex differences in bullying may also be useful for informing anti-bullying programs and improving intervention outcomes to reduce bullying within schools.

Intervention and Implications

Current anti-bullying interventions have often focused on increasing the costs of bullying (e.g., punishing bullies to change their behavior), while failing to recognize the motives or goals that underlie much of bullying (Ellis et al. 2015). School disciplinary policies using this approach may not reduce bullying, and in some cases may actually increase the frequency of the behavior (see Ellis et al. 2012). However, adopting an evolutionary perspective of bullying highlights both

the salient costs and benefits of bullying, which tailors the intervention to the specific goal-directed nature of bullies (Ellis et al. 2015). Ellis and colleagues (2015) have proposed a new, evolutionary-inspired bullying intervention, Meaningful Roles, which takes into account the cost-benefit model of bullying and consists of two components. First, bullies are provided with meaningful roles and responsibilities such as giving them "jobs" within the school (e.g., being a door-greeter). Next, students receive positive peer feedback for exhibiting prosocial behaviors. Considering that bullies may not be willing to give up a behavior that results in favorable outcomes (Volk et al. 2012), Meaningful Roles is focused on creating a positive school climate by reducing bullying through prosocial options that still allow bullies to achieve their goals without needing to resort to antisocial behaviors (Ellis et al. 2015). Most importantly for this topic, the roles chosen to be used can be tailored to sex-specific goals that can better accommodate the goals and desires of male bullies.

Conclusion

An evolutionary approach that emphasizes the adaptive function of aggression, particularly for males' reproductive fitness, may serve to help better understand why males bully more than females. Sexual selection may provide the most complete understanding for sex difference in aggression (Archer 2009), which may also inform sex differences in bullying. Diverging levels of parental investment and reproductive variability between males and females (Geary 1998) may underlie much of the sex differences in bullying – the heightened propensity for males to engage in more physical bullying than females. In addition, males may also have physical adaptations that prepare them for direct conflict over access to mates (Georgiev et al. 2013). Therefore, bullying may have evolved as a sexual strategy for males, more than females, to compete with rivals for sexual opportunities. As such, anti-bullying interventions need to be cognizant of the evolutionary

function of bullying to obtain goals and focusing on redirecting bullies toward more gender-appropriate prosocial alternatives to obtain similar goals (Ellis et al. 2015), particularly as it relates to sexual selection involving male and female intrasexual competition.

Synonyms

[Aggression](#); [Peer victimization](#)

Definition

Physical bullying is a direct form of bullying that involves overt acts of physical aggression, such as hitting, kicking, and shoving. Physical bullying is goal-directed, can cause significant harm, and occurs within the context of a power imbalance (Volk et al. 2014).

Introduction

Being involved in bullying, (especially as a victim) can lead to negative mental health outcomes, such as anxiety and depression (Volk et al. 2012). Until recently, bullying was considered to be a product of a maladaptive development (Volk et al. 2012). However, a maladaptive development cannot easily account for the prevalence of bullying across cultures and history (Volk et al. 2012). This has encouraged researchers to suggest that bullying has evolved as an adaptive strategy that uses aggression to obtain gains in three major evolutionary goals: reproduction, reputation, and resources (Volk et al. 2012, 2014). Research has demonstrated that, typically, boys engage in more physical bullying while boys and girls engage in roughly equal levels of relational bullying (Volk et al. 2006). In order to understand why boys engage in more physical bullying, it is essential to examine the evolutionary function behind physical bullying for males.

Why Do Males Engage in More Physical Bullying?

Men and women encounter different adaptive challenges regarding their ability to successfully produce offspring. The most significant challenge to men's reproductive success is the limited number of fertile women. Fertile women are less available because of the higher levels of maternal versus paternal investment in offspring (e.g., gestation and breastfeeding; Gangestad and Simpson 2000). On the other hand, the major challenge to women's reproductive success is to find a mate with the motivation and ability to provide and invest resources in them and their offspring (Buss and Schmitt 1993; Gangestad and Simpson 2000).

In order to adapt to these challenges, men and women have developed different sexual strategies for "selecting, attracting, and maintaining a mate" (Ellis et al. 2012, p. 601). Overcoming these challenges is essential for reproductive success. Therefore, men and women have evolved to prefer specific traits in the opposite sex as a resolution to these constraints (Geary 2010). Due to females' higher parental investment, females have evolved as the more selective sex and thus more emphasis is placed on female mate preferences. Women have developed two major mate preferences in order to adapt to the challenges they face in regards to reproductive success. The first preference is a mate who is capable of providing resources. This preference can be displayed in qualities such as ambition, income, education, and social status (Geary 2010). The second preference is genetic fitness, so that their offspring can inherit good genes. Indicators of genetic fitness include a tall and muscular frame, physical strength, and attractiveness (e.g., facial symmetry) (Geary 2010). This means that women are more focused on attracting a mate versus depriving other women of their mates (i.e., polyandry).

On the other hand, men can greatly benefit from depriving other men of their mates (polygyny) as their reproductive success is constrained by the limited availability of fertile women. This means there is greater variance in male's reproductive success as they are more

likely to be on the end of two extremes: either having no children or having many children (Volk et al. 2012). As a result, males compete for access to fertile females and must then engage in risky forms of competition to ensure reproductive success (Geary 2010). Males expend much of their reproductive effort into competing against other males for mates (Geary 2010). Men can also afford to engage in riskier forms of competition as they are not obligated to invest in their offspring to the same degree as females (Volk et al. 2012). For example, if a father dies during a fight, their death has fewer consequences on the survival of their offspring as the mother is the main caregiver. In contrast, maternal death strongly influences child mortality, in which infants are more likely to die as a direct result of their mother's death (Sear and Mace 2008).

In this way, physical bullying has many evolutionary functions for males. Physical bullying provides males with the opportunity to show off the preferred traits to potential mates (Volk et al. 2012). Physical bullying requires the bully to use physical strength to exert power over the victim. By using physical strength to bully, males are demonstrating an indicator of genetic fitness (Gangestad, and Simpson 2000). Physical bullying in particular can be a means to directly obtain resources and thus demonstrate their ability to provide for their mate and offspring. In addition, by obtaining more somatic resources, bullies have the necessities to grow larger in size, which is also an indicator of genetic fitness (Volk et al. 2012).

A male's social status can also be a means of demonstrating their ability to provide resources and to increase their access to more potential mates (Geary 2010). By using physical bullying, males can employ dominance in the social hierarchy and gain popularity. Being at the top of the social hierarchy can lead to many benefits; for example, having more control over resources and more access to potential mates (Volk et al. 2012). Furthermore, males engage in physical bullying as a way to enhance their social status. Bullies attempt to create a reputation that signals to other competitors that they are "tough" in order to deter retaliation (Ellis et al. 2012).

Physical bullying has also evolved as an effective strategy to compete with other males for access to potential mates (Volk et al. 2012). Adolescence in particular is marked by an increase in male to male competition, as adolescents become capable of reproduction and begin to date (Geary 2010). As a result, physical bullying is most prevalent during this age period (Volk et al. 2012). Physical bullying is considered to be a higher risk strategy as it is directly observable and requires physical contact, which can easily lead to detection or to serious injury and even death (Volk et al. 2012). Males will use physical bullying as a way to strengthen bonds between in-group members. When in-group members assist in bullying, they demonstrate their allegiance to the group (Volk et al. 2014). Males will also use physical bullying to target out-group members. With a dedicated group of allies, males demonstrate their ability to protect their mates and offspring.

Conclusion

In order for bullying interventions to be effective, they must first acknowledge that bullying is used as an adaptive strategy to obtain somatic, social, and sexual benefits and work towards increasing the cost of bullying, while still providing alternative prosocial strategies that will lead to these same benefits (Ellis et al. 2015). Therefore, to reduce the rates of physical bullying among males, it is pertinent to consider the evolutionary functions behind this behavior and to provide alternative methods to accomplish the previously mentioned goals of physical bullying.

One of the main characteristics of physical bullying that should be addressed in interventions is that it is an overt form of aggression that can be easily detected. To avoid detection, adolescent males tend to engage in physical bullying in places that have low adult supervision; for example, the playgrounds, hallways, and bathrooms in schools. In addition, teachers or other school staff who do witness physical bullying may not identify it as bullying but instead attribute the behavior to the “boys will be boys” ideal. Without adult

intervention, this ideal reinforces physical bullying as accepted behavior. For example, in hunter-gatherer societies, physical bullying is not a common occurrence due to frequent adult intervention and because it is not considered as a social norm (Volk et al. 2012). Therefore, the first step to reduce physical bullying is to increase adult supervision. This can include increasing the school staff during recess, having hall monitors or installing video surveillance, and educating parents and teachers on how to identify physical bullying. When weighing the costs versus benefits to engage in physical bullying, an increase in the possibility of being detected will be an additional consequence the perpetrator must consider.

Adolescents have learned to use physical bullying as an effective strategy to obtain benefits in resources, reputation, and reproduction. To date, bullying interventions have failed to make a significant impact in reducing bullying because they demand adolescents to give up bullying without providing any alternative strategies. An intervention entitled “The Meaningful Roles Intervention” is designed to implement alternative prosocial strategies for achieving adaptive goals (Ellis et al. 2015). This intervention incorporates two major components: a job program, in which students are provided with meaningful responsibilities, and a praise note system, in which students publically praise students for engaging in prosocial behavior (Ellis et al. 2015). These two components provide students with the opportunity to use prosocial strategies to obtain social status by publically contributing to the group in a prosocial manner and by creating a positive reputation for engaging in prosocial behavior (Ellis et al. 2015).

The second evolutionary function of physical bullying is to demonstrate genetic fitness (Geary 2010). As previously stated, physical bullying is used as a strategy to publically display physical strength (Gangestad and Simpson 2000). An alternative method for demonstrating physical strength that has a lower cost but still accomplishes the same goal is participation in competitive sports, as they publically demonstrate physical strength and skill (Volk et al. 2012). Bystanders can also be encouraged to use their

physical strength to defend victims, as this is also a display of genetic fitness through prosocial behavior (Volk et al. 2012).

The third evolutionary function that was discussed was using physical bullying to compete for potential mates by strengthening allies and targeting competitors (Volk et al. 2012). An intervention that has been relatively effective in increasing the cost of bullying is called the KiVa program (Ellis et al. 2012). This program focuses on devaluing bullying in the peer group by teaching adolescents how they can be indirectly supporting peers who bully by rewarding their aggressive behavior. This program also focuses on increasing the cost of bullying by encouraging bystanders to intervene more frequently (Ellis et al. 2012). In summary, in order to reduce physical bullying among males, interventions must work with the goals of bullying by replacing the aggressive strategies with prosocial strategies that are just as effective in obtaining gains in resources, reputation, and reproduction (Ellis et al. 2015).

Boys' Rough-and-Tumble Play

Lindsay A. Coome

University of Toronto, Toronto, ON, Canada

Introduction to Rough-and-Tumble Play

Rough-and-tumble play (R&T) refers to physically vigorous behaviors such as wrestling, chasing, pushing, and so on, that are primarily playful, not aggressive. R&T is observed in most mammals and accounts for about 10% of their time and energy resources (Bjorklund and Pelligrini 2002). In humans, it emerges around 3 years of age and has been documented in every culture in which it has been studied (Byrd-Craven and Geary 2007). The development of R&T play follows an inverted U-shaped pattern, with R&T frequency peaking at roughly 8–10 years of age (Pelligrini

and Smith 1998), and then declining in frequency at puberty. It has generally been assumed to have a function, and several functional hypotheses have been proposed to explain R&T. Broadly, functional hypotheses may be distinguished by whether they hold that the functional (survival or reproductive) benefits of R&T are immediate or delayed.

Sex Differences in Play

Robust sex differences are found in R&T, with males engaging in it more frequently than females in many mammalian species and nearly all human cultures (Bjorklund and Pelligrini 2002). Androgens, such as testosterone, have been implicated in producing these sex differences, and higher testosterone is associated with higher levels of R&T in males (Graham and Burghardt 2010). Rough-and-tumble play generally occurs more often in polygynous and/or gregarious species than monogamous or solitary species, and in the sex that competes for mates and resolves social conflict through physical aggression or contests in adulthood (Byrd-Craven and Geary 2007). Indeed, the sex difference in frequency of R&T in children strongly favors boys, and it has thus been proposed that sex differences in R&T play reflect sex differences in intrasexual competition during human evolution and serve to provide the practice needed to develop competitive or fighting skills.

Rough-and-Tumble Play as Training for Fighting Skills

On this view, R&T can serve as practice for species-specific behaviors that facilitate survival or successful reproduction in adulthood, especially when direct practice of that behavior, such as fighting, might be dangerous or costly. R&T play during the juvenile period might then serve as motor training or practice for fighting. If the purpose of R&T is training for fighting skills, sex or individual differences in frequency of R&T ought to be reflected in later developmental outcomes (Smith 2007).

There is little direct evidence linking R&T in youngsters to serious fighting ability in adulthood, however. While play may enhance physical fitness, many effects of exercise are not long lasting, which suggests that adults should also engage in R&T. It has been suggested that play might facilitate the development of appropriate muscle fiber types, however this view has received little experimental support (Graham and Burghardt 2010). Furthermore, critics of this view contend that play fighting is not effective or valuable practice for serious fighting. A critical aspect of fighting in squirrel monkeys, for instance, is the inflicting of bites (Biben 1998); however, real or inhibited biting is absent from play fighting in this species, making it perhaps an imperfect model for learning how to fight effectively. In rats, too, play fighting does not resemble aspects of real fighting in important ways. During serious fighting, rats compete for access to the rump and lower flanks of their opponent's body, which are bitten on contact (Pellis and Pellis 2007). During play fighting, rats compete for access to the nape of their play partner's neck, which is nuzzled on contact. Some motor patterns useful for combat are present in play; however, it has been argued that some of the characteristics that make R&T playful rather than aggressive are in fact counterproductive to learning how to fight effectively, including the inhibition of wounding, self-handicapping, and role-reversals that characterize R&T in many species. As motor skills are practiced effectively only through faithful reproduction of that motor pattern, it seems unlikely that play serves as a means for practicing specific skills, such as fighting.

Rough-and-Tumble Play for the Development of Cognitive Skills and Social Competence

While the evidence for R&T as motor skills training or practice for combat in adulthood is lacking, evidence suggests that R&T might be necessary for the development of social competence, especially the kinds of competencies that might be useful for later agonistic encounters. During R&T, dominant or older players often self-handicap so that their partners can assume a

superordinate position (i.e., the player who pins the other) and they can gain experience in a subordinate one (Bjorklund and Pelligrini 2002; Biben 1998). For example, it has been suggested that opportunities to gain experience in both a subordinate and superordinate role are important for juvenile squirrel monkeys, with animals not receiving enough experience in either role growing up to be bullies or thin-skinned, respectively. Therefore, gaining experience in both of these roles may relate to developing social competence.

Studies that have attempted to deprive young animals of play may lend support for the view that R&T helps facilitate the development of social competence. Play deprivation studies often suffer from the complication that successfully eliminating play may depress other social behaviour as well. However, experiments aimed at disentangling the effects of play deprivation from general social deprivation suggest that experience in R&T play is critical for the development of cognitive, emotional, and social competency in rats. When juvenile rats are deprived of opportunities to engage in R&T play, they exhibit social and cognitive deficits, most notably hyperdefensiveness to the approach of another animal and difficulty coordinating movement during sexual or competitive encounters with a social partner, along with impairments in solving various cognitive tasks (Pellis and Pellis 2007). R&T play-deprived rats appear to be overly stressed by novel encounters and socially inept at responding to them. Rats reared in pairs with mesh partitions between them preventing them from engaging in R&T still had cognitive and social deficits in adulthood. The same was true for juvenile rats reared in the same cage as an adult or a drugged juvenile littermate incapable of R&T, an arrangement that provides the opportunity for social contact but not for R&T play. However, when juvenile rats reared in isolation were given access to an age-matched partner for one hour a day, the rats engaged in play fighting for most of that hour and did not show cognitive deficits as adults. Rats reared with littermate siblings engage in R&T play for roughly an hour a day, and so it is perhaps unsurprising that an hour of daily access to R&T play is sufficient to prevent the cognitive

deficits associated with play deprivation. It has been suggested that experience with the juvenile-typical pattern of R&T play may provide feedback to the brain structures responsible for generating such play, which then promotes the development of those structures (Pellis and Pellis 2007). Two such areas are the orbitofrontal cortex (OFC) and the medial prefrontal cortex (mPFC), which are involved in modifying behaviors to different partners, and coordinating movements with a social partner, respectively (Pellis et al. 2010). Juvenile play fighting is thought to induce the release of growth factors in this area, and rats with damage to these structures exhibit the same social deficits that play-deprived rats do (Pellis and Pellis 2006). Thus, it seems that experience in juvenile R&T is a critical component of normal social development, possibly through its influence on the development of relevant areas of the brain.

Given the similarities between R&T in humans and nonhuman animals, it is possible that R&T experience in childhood promotes the development of social competence in adulthood in humans, too. Indeed, evidence from primate studies suggests that the effects of play deprivation in monkeys are similar to those seen in rats. Harlow's social deprivation studies with rhesus monkeys, wherein infant monkeys were reared with only a terry cloth mother, led to animals with severe sexual and social deficits (Pellis and Pellis 2006). However, when these animals were given 30 minutes of contact with peers, monkeys with terry cloth surrogates did not show such social deficits in adulthood. While these studies do not directly address the relative contributions of play versus general social deprivation, social isolation in monkeys reveals a similar pattern of social deficits to those seen in rats: hyperdefensiveness to social stimuli the isolated monkeys perceive as threatening, and difficulty coordinating movements and behavioral sequences effectively with a social or sexual partner.

In humans, there is a relationship between R&T and social competence. During childhood, R&T play in boys is positively associated with measures of popularity and friendship. Chasing and fighting, two aspects of R&T play, are positively related to peer acceptance for boys but not girls. Boys who

engage in more play fighting are more popular, better at solving social problems, and are more flexible on the playground (Pelligrini and Smith 1998). It has been argued that certain features of R&T, such as self-handicapping and role-reversals, facilitate the acquisition of flexibility in behavior in children, which is useful for social problem solving. It is plausible, then, that the relationship between R&T and social competence is causal. Moreover, longitudinal studies have revealed that R&T play predicts children's later emotional expressiveness and emotion regulation (Lindsey and Colwell 2013).

Conclusion

Thus, a large body of evidence from rodents and primates links peer-to-peer R&T as juveniles to later social competence and emotional regulation skills. Humans are social animals, and so developing the social competencies necessary to adapt to the complexities and challenges of group living seems important from an evolutionary perspective. However, despite its obvious benefits, more direct tests of whether R&T play improves survival or reproduction in humans are needed. Moreover, even if R&T has no current adaptive benefit, this does not mean that such play was not subject to selection in the past. Different aspects of play might have current or past adaptive benefits. In addition, more research is needed to determine which aspects of R&T play are necessary to produce improvements in these skills. Despite this, the evidence largely supports the development of emotional and social competency as a likely function of R&T play.

Brain at Birth

Andrew C. Halley
University of California Davis, Davis, CA, USA

Synonyms

[Neonatal brain size](#); [Neonatal brain/body allometry](#)

Definition

The absolute size, relative size (brain/body ratio), and stage of neurodevelopment in a species' brain at the time of birth.

Introduction

The size and developmental stage of the newborn brain is highly variable across different mammalian species. For decades, the state of mammalian brains at birth has been the focus of great interest by researchers in developmental and reproductive biology, biological anthropology, and the evolution of life history. Although methods for comparing species' brains at birth have varied widely, two major approaches have generally been used to examine birth timing and mammalian brains at birth. First, thanks to several large datasets (e.g., Sacher and Staffeldt 1974; Harvey and Clutton-Brock 1985), neonatal brain size, body size, gestation length, and similar variables have been analyzed by researchers in anthropology, life history, and evolutionary biology. A second approach uses more detailed analyses in a smaller numbers of species – particularly model species in developmental biology, where more detailed data are available – to focus on brain growth and development during fetal and early postnatal stages of ontogeny. These complementary approaches have increased our understanding of when species are born during neurodevelopment, and how this affects the early postnatal development of their offspring.

Caution is warranted in any discussion of “neonatal brain size” for one simple reason: birth does not align different species at similar time points in either neurodevelopment (i.e., the highly conserved order of neurogenesis, axon extension, myelination, etc.) or in the growth of the brain (e.g., changes in brain size over time, or brain/body proportions over time). Instead, birth captures a single cross section in the dynamic process of neurodevelopment, and that snapshot is taken from different moments depending on which species is under consideration. This has led numerous commentators to critique the use

of birth as an anchor point to compare different species' neurodevelopment (Newell-Morris and Fahrenbruch 1985; Finlay and Workman 2013; Halley 2017).

If species' brains are so different at birth, what can we reasonably learn from studying brains at this seemingly arbitrary time point? In fact, a central variable in evolutionary life history relies almost entirely on birth timing: whether a given species is altricial or precocial at birth. Briefly, altricial species are born in a relative stage of somatic and neurological immaturity, and undergo a larger portion of brain development after birth. Precocial species complete a greater portion of neurodevelopment prenatally and are born in more mature states. Examining how birth timing differs between altricial and precocial species can help to explain one of the most important evolutionary features of human brain development: our species' unusual degree of altriciality among primates.

How Large Are Mammalian Brains at Birth, and Why?

The smallest neonatal mammalian brains are less than 1/10th of a gram, and are found in small marsupials (which give birth to extremely immature embryos) and rodents. By contrast, an African elephant (*Loxodonta africana*) newborn brain is more than 1600 g, on the larger end of the range of adult human brains (Sacher and Staffeldt 1974). As we might expect, these differences in neonatal brain size reflect differences in the adult brains they will become – there is a roughly linear relationship between neonatal and adult brain size when these variables are shown in log-log form (Martin 1982; DeSilva and Lesnik 2008). Nevertheless, some species have smaller neonatal brain sizes than we should expect for mammals of their adult brain size (Fig. 1). Where does this variation come from?

First, it is important to understand how evolution alters neurodevelopment to produce brains of differing size. Larger brains are generally produced by stretching out the process of neurodevelopment over time – that is, by delaying

Brain at Birth, Fig. 1 Neonatal brain size vs. adult brain size in a sample of 103 placental mammals. Neonatal brain size and adult brain size are highly correlated, with larger brained species giving birth to larger brained newborns. However, species that give birth to larger litters tend to be born earlier in neurodevelopment (i.e., altriciality, solid green circles) when compared to species born later in neurodevelopment (i.e., precociality, open red circles). Because birth is pushed forward relative to neurodevelopment in altricial species with large litters (black arrow), they have smaller neonatal brain sizes even when adult brain sizes are similar. For example, altricial species' neonatal brains are a lower percentage of adult brain size (~16%) compared to precocial species (~43%). OLS regression models are shown through precocial ($n = 75$) and altricial species ($n = 28$). Dataset from Halley 2016 (original sources listed in that paper)

the onset of neurogenesis from progenitor cell populations, the processes of axon extension and pruning, and the myelination of axons fibers and the tracts they compose (Workman et al. 2013). This means that generally speaking, at any given fetal or neonatal brain size, a large-brained species will be at earlier neurodevelopmental stages than a smaller-brained species. A two gram rat brain belongs to a mature animal, while a two gram human brain (~115 days gestation) is still undergoing primary cortical neurogenesis (estimated from data in Halley 2017).

Mammalian brain growth exhibits a characteristic sigmoid (s-shaped) pattern over time since conception, consisting of (1) an early, largely fetal period of exponential growth; (2) an inflection point of peak growth velocity, when brains are growing at their fastest in mass per day; and (3) a deceleration phase of slower brain growth resulting in a mature adult brain (Halley 2017; Fig. 2a, b). Just as the schedule of neurodevelopment is stretched out to build a larger brain, this characteristic pattern of brain growth is also extended. Birth is highly variable across species relative to this general growth pattern. Dobbing and Sands (1979) originally described variation in birth timing around peak growth velocity, which they called the “brain growth spurt.”

Generally, altricial species are born before peak velocity, and precocial species are born after it; this is because peak growth occurs at a similar time to eye opening (Halley 2017; Fig. 2e), a crude but useful method for distinguishing species born earlier or later in neurodevelopment.

The most altricial mammalian species are marsupials, which are born in an embryonic state and undergo most of neurodevelopment postnatally during a period of lactation and weaning (Ashwell et al. 1996; Renfree et al. 1982). For example, the short-tailed opossum *Monodelphis domestica* is born after only 14 days of gestation, and due to their unusually slow rate of brain development, they are only beginning to undergo cortical neurogenesis by the time they are born (Puzzolo and Mallamaci 2010). By contrast, the most mature (precocial) species at birth tend to be placental mammals with a single offspring per gestation period. Examples include many ungulates (e.g. horses), which can locomote shortly after birth. Precocial species are born during later stages of neurodevelopment with more mature sensory and motor systems, generally after neurogenesis is largely complete – a period characterized by myelination of existing connections and the pruning of synaptic connections between brain areas (Sherwood and Gomez-Robles 2017).

Whereas larger brains are the consequence of stretching out both growth and developmental

Brain at Birth, Fig. 2 Simplified diagrams of birth timing vs. brain growth, brain/body growth, and neurodevelopmental events. (a) Brain growth in mass over age since conception (i.e., growth velocity) exhibits a sigmoid pattern of growth, consisting of exponential growth, peak velocity, and deceleration phases. Altricial species are born earlier along this trajectory, and precocial species are born later. (b) Growth velocity in mass per day changes over development, reaching its highest point at peak velocity. This is the derivative of the function shown in a. (c) Brain/body ratios generally decrease over development, though some species with exceptionally slow body growth (e.g., primates) have retained higher proportions for longer periods of time. After peak velocity of brain growth, brain/body ratios decrease. As we saw with brain velocity, species differ in the timing of birth relative to brain/body

allometry over development. (d) The same relationship shown in c, now in log-log coordinates that are commonly used to analyze developmental allometry. (e) Birth timing of several mammalian species, plotted against a highly conserved pattern of neurodevelopment. The x-axis represents a standardized 0–1 score of neurodevelopmental events (from Workman et al. 2013), with zero representing the start of brain development and one representing a fully mature brain. Marsupials are born in an extremely immature, altricial state, around the onset of neurogenesis in the neocortex. All eutherians are born later in neurodevelopment, with more altricial neonates born earlier (prior to eye opening) and all precocial neonates born later (after eye opening). Humans are more altricial than other primate species (see main text)

patterns over longer periods of time, most eutherian species seem to grow their brains at similar rates (i.e., growth acceleration) over the early exponential period of development when most of neurogenesis is underway (Passingham 1985; Deacon 1990; Halley 2017). Notably, species with larger adult brains or with larger neocortices (like primates [Barton and Harvey 2000]) do not appear to exhibit faster brain growth during this period than smaller-brained mammals. Similarly, species with larger brain/body ratios than other mammals of similar body size (i.e., “encephalization”), either at birth or as adults, do not have faster brain growth *in utero* (Halley 2017). Only a few groups of mammals seem to exhibit unusually slow brain growth (e.g., marsupials [Renfree et al. 1982; Halley 2017] and bats [Martínez-Cerdeño et al. 2017]), for reasons that remain poorly understood.

Because more altricial species are born earlier relative to neurodevelopment (Fig. 2e) and brain growth (Fig. 2a), they are born with brains that compose a smaller fraction of the adult brains they will become. Figure 1 shows neonatal brain size compared against adult brain in a sample of altricial ($n = 26$) and precocial ($n = 75$) species, with larger data points indicating litter size. We can clearly see that altricial species are born in larger litters, and both variables are associated with having a smaller neonatal brain relative to adult brain size. The same effect can be seen in comparing neonatal brain size vs. adult body size – altricial species exhibit smaller neonatal brains than we should expect (Pagel and Harvey 1990). If we assume that similarly-sized adult brains are produced from similar brain growth patterns (Halley 2017), these findings are the consequences of earlier birth in altricial, large-litter species (black arrow) causing them to be born at a smaller proportion of adult brain size – and at earlier stages of neurodevelopment.

A number of studies have examined early postnatal brain growth patterns across anatomically modern humans and our phylogenetic relatives (e.g., Neanderthals [Ponce de Leon et al. 2008],

chimpanzees [Sakai et al. 2013], and other extant primates [Leigh 2004]) in order to determine how human brain growth patterns evolved. While we should expect larger brains to exhibit extended brain growth and development patterns, analyses of postnatal growth alone can be misleading. Humans do exhibit faster postnatal brain growth than other primates (Leigh 2004; Ponce de Leon et al. 2008), but this is not unexpected – larger brains always achieve higher growth velocities, since the period of exponential growth is longer, and peak velocity is reached at a larger brain size (Halley 2017). The larger problem with analyzing postnatal patterns in isolation (an unavoidable problem when fetal data are unavailable, either in extant or fossil species) is that birth does not align similar parts of different species’ sigmoid brain growth trajectories (Fig. 1). It therefore becomes unclear whether postnatal growth patterns are sampling similar or different parts of a given brain growth pattern (e.g., acceleration or deceleration phases). For example, Sakai and colleagues found that humans exhibit larger increases in white matter proportions than chimpanzees or macaques during early postnatal life (Sakai et al. 2013) – but these changes do not result from a unique human growth phase, but instead as an artefact of using birth as a temporal anchor (Finlay and Workman 2013).

How Large Are Mammalian Brain/Body Ratios at Birth, and Why?

Human brains are exceptionally large within the primate lineage, but humans do not have the largest mammalian brains – whales and elephants have brains that dwarf the human brain in absolute mass (Crile and Quiring 1940). Humans also do not have the largest brain/body ratios within the mammalian radiation – these belong to the smallest mammals, given that brain/body ratios are smaller in larger animals (i.e. Haller’s rule). Primates generally and humans specifically are

only unique among mammals in exhibiting unusually high brain/body proportions once body size has been taken to account (i.e., “encephalization”). This has led many researchers to ask whether neonatal brain/body proportions – rather than absolute brain size – might be unique within primates.

Whereas the growth of the brain or body against linear time since conception follows a regular sigmoid (s-shaped) growth pattern (Fig. 2a), brain/body proportions over ontogeny generally decrease over fetal and postnatal development (Fig. 2c). When we plot an individual species’ brain/body proportions over development using log-log coordinates (as is customary; cf. Count 1947; Halley 2016), what emerges is a characteristic two-stage growth pattern that is common to all mammalian species that have been studied (Fig. 2d). During early prenatal development, both brain and body growth are exponential, and brain/body ratios tend to either stay fairly constant (isometric growth) or decrease slightly (negatively allometric growth) (Fig. 2d). This variation has been directly linked to differences in species’ body growth (Halley 2017). Briefly, species that decrease in brain/body proportions more over development tend to have faster body growth, rather than slower brain growth (Halley 2016). In all species, this early period of brain/body growth comes to an end as brain growth reaches “peak velocity,” or the fastest period of brain growth in grams per day (Fig. 2a). Once peak velocity has passed, brain/body ratios fall dramatically, continuing to do so until the organism is fully mature (Fig. 2c).

Primates are unique among mammals in exhibiting unusually high brain/body proportions across all of prenatal development, a developmental feature that is also true at birth (Count 1947; Holt et al. 1981; Martin 1982; Deacon 1990; Halley 2016). Primate prenatal “encephalization” is apparently unrelated to either adult brain/body proportions or the relative size of the neocortex within different primate species (Halley 2016). Analyses of fetal growth patterns in primates suggest that high fetal and neonatal brain/body proportions are a consequence of primates’ exceptionally slow *body* growth, rather than

exceptionally rapid *brain* growth (Halley 2017). Slow body growth has also been observed in primate postnatal development (Leigh 2004), and appears to be linked to their exceptionally slow life histories (Harvey and Clutton-Brock 1985).

Similar to brain growth over time, altricial species are born earlier along brain/body growth plots when compared to precocial species (Halley 2016). Roughly speaking, brain/body proportions tend to decrease over development, and so altricial species tend to exhibit higher brain/body ratios at birth. The major exception to this pattern is seen in primates, which are precocial and exhibit high brain/body proportions at birth linked to slow body growth (see above). The large degree of variation in both birth timing and body growth rates between mammalian species make neonatal brain/body proportions a complicated measure to interpret, and they should not be taken as proxies for fetal brain growth patterns or neurodevelopmental stage in comparative studies (Halley 2017).

Human Neonatal Brain Size and Secondary Altriciality

One of the central questions in human evolution concerns our species’ relative altriciality among primates: human neonates are born at earlier stages of neurodevelopment than other primates are. While primates are generally considered to be precocial at birth in comparison with other mammalian radiations – meaning we have relatively long gestation, small litter size, and are born more mature than other mammals are – humans are nevertheless at the altricial end of the primate spectrum. Humans are born at earlier stages of neurodevelopment than other primates (Sherwood and Gomez-Robles 2017), and have grown a smaller proportion of their adult brain size by the time of birth (Harvey and Clutton-Brock 1985; Martin 1982). This phenomenon has been called “secondary altriciality” and is thought to contribute substantially to our species’ exceptional degree of neuroplasticity in early postnatal life (Sherwood and Gomez-Robles

2017). The most straightforward explanation of human altriciality is that evolutionary increases in human brain size since the last common ancestor with chimpanzees (Kaas and Preuss 2013) required longer periods of neurodevelopment, and that human gestation did not lengthen proportionate to this change in the duration of brain development.

A central theory for human altriciality is that in the course of human evolution, shortening of the pelvis to accommodate the biomechanical demands of bipedal locomotion led to difficulty in fitting the neonatal head through the birth canal. According to the “obstetric dilemma” theory, these complications led to evolutionary pressure to shorten gestation in the human lineage, causing human neonates to be born “early” and causing our exceptional degree of altriciality at birth (e.g., Washburn 1960; Rosenberg and Trevathan 1995). A number of critiques of this widely cited theory have been raised in recent years. First, human gestation is not unusually short for a primate of our maternal body size (Dunsworth et al. 2012), only relative to neurodevelopment. It is unclear why brain development should be the benchmark by which to measure “proper” gestation length or deviations from it, given how variable birth timing is across mammals relative to brain growth (Halley 2017) and neurodevelopment (Workman et al. 2013). Second, human encephalization has been the evolutionary product of increases to brain size. Given that larger brains are grown by extending the *duration*, rather than the *rate* of brain fetal brain growth (Halley 2017), it is not surprising that evolutionary increases in brain size necessitate longer neurodevelopmental periods. This should make human brains smaller at birth, as a percentage of adult brain weight, even if gestation length has been held perfectly constant. A critical review and alternative hypothesis to the “obstetric dilemma,” focusing on metabolic demands of pregnancy rather than pelvic constraints, was recently proposed by Dunsworth and colleagues (Dunsworth et al. 2012).

Regardless of whether human altriciality is a consequence of birth constraints or simply lengthening our period of brain growth and development, humans’ relative degree of altriciality has

important consequences for early cognitive development, and even for certain features of human culture. One example is the prevalence across human cultures of “alloparenting,” or cooperative breeding (Hrdy 2011), including traditions associated with assistance during parturition (birth assistance, midwifery) and in cooperative child rearing (e.g., Trevathan 1987). While some nonhuman primates may seek the company of conspecifics during birth, both the degree and the prevalence of birth assistance in humans seem sufficient to consider it a behavior unique to our species. Finally, the exposure of human infants to the external environment during relatively plastic stages of brain development (e.g., synapse formation and pruning) likely plays a central role in our species’ unique degree of behavioral flexibility (Sherwood and Gomez-Robles 2017).

Conclusion

Mammals differ widely in the timing of birth relative to both brain growth and brain development. Generally speaking, smaller mammals with larger litters are born earlier along brain growth patterns, earlier in neurodevelopment, and earlier along brain/body allometric trajectories. Larger-brained placental mammals, or more encephalized species as adults or at birth, do not grow their brains faster during gestation, but do exhibit a slower pace in the timing of neurodevelopmental events. Species born earlier during neurodevelopment are generally altricial, with relatively immature young. While primates are more precocial compared to other mammals, humans exhibit an exceptional degree of altriciality relative to other primate species. This is likely a consequence of the extended neurodevelopmental schedule required to build the largest extant primate brain, rather than a shortening of gestation length in human evolutionary history. Human altriciality exposes the newborn brain to environmental stimuli during earlier stages of brain development, contributing to an exceptional degree of plasticity in our species that can be linked to unique features of human reproduction and perinatal care.

Introduction

The human brain is arguably the ultimate result of natural selection. It is the most complex organ in the human body with approximately 100 billion neurons and over 100 trillion synaptic connections. This basic description does not include the billions of supporting cells or the complex genetic, hormonal, chemical, and electrochemical interactions that are constantly occurring. The brain gives rise to our sensations and perceptions, houses our memories, and more generally directs our behavior. Therefore, understanding how the human brain develops is of great interest and importance to many fields of psychology. Generations of scientists have examined brain development in humans and other animals by utilizing our understanding of evolution and shared phylogenetic properties. This entry provides an overview of brain development from conception to late adolescence and provides examples of the various environmental and genetic factors known to impact the developmental process.

Definition

Brain development, which occurs rapidly early in life but continues throughout life, involves the interplay of genetic expression and environmental impacts on the growth and maturation of neurons and the connected networks they form.

Stages of Neuron Development

We now have a good understanding of the basic stages and mechanisms of mammalian brain development (Stiles and Jernigan 2010). Studies describing the neurobiology of brain development range from the neural organization of the entire brain to the cellular level of neurons, and on to the molecular level of various genetic and chemical factors. Together, this research finds that brain development results from the dynamic interplay of factors that are constrained by genetics but affected by a constantly changing experiential and environmental context. In order to discuss the influence of genetic, environmental, and other factors on brain development, it is important to first understand the basic progression of neurons from stem cells to maturity. Although neurons are not the only important cells in the brain, they are the fundamental functional unit of nervous tissue that transmit and receive nerve impulses (Pinel and Barnes 2018).

Following conception, the zygote is comprised of a mass of undifferentiated cells. Through genetic and chemical factors, this mass of totipotent cells begins to differentiate into the cells that will form different tissues in the body. Cells destined for the brain progress to a more specific class of pluripotent cells and then finally a multipotent form that can divide readily into different types of neurons (Kohwi and Doe 2013). The first recognizable structure of the early brain is known as the neural plate. This plate can be further divided into an outer ectoderm layer, a middle mesoderm, and an inner endoderm component. Chemical signals, which are critical to many aspects of neural organization during development, are released from early cells in the mesoderm layer (Kiecker and Lumsden 2012).

The stem cells of the neural plate proliferate rapidly in the first trimester in humans. This rapid growth initiates a folding of the neural plate into the neural tube. Interestingly, this early folding into a tube shape forms the fluid filled inner space which will develop into the ventricles and also begins to symmetrical hemispheric organization of the mature brain (Pinel and Barnes 2018). The immature neurons continue to divide rapidly during this phase in the layer directly adjacent to the early ventricle. This so-called ventricular zone forms the foundation for the neural layers and structures that will form above.

Once the ventricular layer/zone is formed, the neurons begin to migrate away in two different directions. Radial migration involves the immature cells moving directly up from the ventricular zone. In this way, subsequent layers of the neuron form on top of each other with newer arrivals settling in the outer most layer of the neural tube. Chemical guidance is critical during this phase so toxins or a lack of natural chemical signals can drastically disrupt the normal migration of neurons (see below). The other form of migration, known as tangential, involves neurons move along the neural tube as opposed to up to the outer layers (see Greig et al. 2013). Glial cells, essential support cells in the brain, are also known to contribute to normal migration by providing scaffolding and path setting for moving neurons (see Ohshima 2015). Although genetic

programming appears to determine the timing and types of chemical signals released, the eventual location and connections of each neuron does not seem to be predetermined.

Once the neurons migrate to various locations, chemical signaling between the cells allows them to aggregate into organized structures. In this way, the early forebrain, midbrain, and hindbrain begin to take shape. Cell adhesion molecules (CAM's) on the surface of the neurons are thought to support the process of aggregation (Mori et al. 2014). These molecules recognize chemical signals on neighboring cells and adhere to them. The brains of genetically modified mice, where these CAMs had been disrupted, showed devastating errors in aggregation and subsequent growth (Lien et al. 2006).

Another important and usually temporary characteristic of neurons during aggregation is the large number of gap junctions that form between cells. As their name implies, these connections are formed from sets of narrow tubes called connexins that directly link the cells and allow cytoplasm to be exchanged (Lien et al. 2006). Hypothetically, this direct exchange allows each cell to confirm chemically that it has ended its migration in a favorable location.

Although the majority of neurons end up in the correct locations, some do not. When this occurs, the aberrant neurons are eliminated via programmed cell death known as apoptosis (Miguel-Aliaga and Thor 2009). This is preferable to the disorganized process of necrosis that results in harmful inflammatory release of cytoplasm into the extracellular fluid. In this way, neurons are initially overproduced with the expectation that not all migration and aggregation will occur successfully. The excess nonfunctional cells are effectively pruned from the brain via apoptosis in a similar fashion to what is observed with synapses (see below).

To this point, the cells have remained immature and lack the connections and electrochemical activity that characterize mature neurons. This begins to occur with the growth of axons (typically sending signals) and dendrites (typically receiving signals). Different types of neurons express different forms of axons and

dendrites but the stages of growth are fairly consistent (see Kerstein et al. 2015). Axons typically begin to grow from the neuron cell body with a fingered structure called the growth cone. These fingers or filopodia are very chemosensitive and essentially smell their way through the growing brain. Pioneering growth cones often form first and lay down a chemical track for subsequent axon growth from neighboring neurons. In this way, tracts or multiple axon bundles form between brain structures in genetically predetermined ways. For example, neurons from the retina follow a chemical pathway created by early axons to connect the eye to the lateral geniculate nucleus of the thalamus and then on to the occipital lobe of the brain which processes vision (see Dudanova and Klein 2013).

While axons are forming, dendrites begin to grow to receive incoming contacts and form synapses. Synapses are the gaps where the nervous impulse passes from one cell to another. This often occurs chemically via the presynaptic release of neurotransmitters and the subsequent activation of postsynaptic receptors. Initially, synapses are thought to form somewhat indiscriminately based on chemical signals shared between the axons and dendrites (see Ou and Shen 2010). This process of synaptogenesis is also facilitated by the presence of glial cells such as astrocytes (Tsai et al. 2012). Astrocytes were initially thought to supply the high levels of cholesterol needed during synapse formation but current theories have been expanded to include astrocytes processing, transferring, and storing chemical information from neurons (see Clarke and Barres 2013). Like neurons, synapses are overproduced in earlier phases of development and are then pruned over time. Synapses appear to undergo a Darwinian-like process where those connections that function and are active based on external and internal stimulation survive while less active or misplaced connections are eliminated (Hebb 1949).

Once the axons and dendrites have been connected through thousands of synapses per neuron and the pruning process is well underway, the final major developmental process of myelination begins to occur. Myelination

involves the wrapping of new axons in a fatty coating that is part of supporting glial cells. This wrapping speeds up the transmission of action potentials (neural signals) by allowing them to jump passively, and essentially instantaneously, between unmyelinated nodes along the axon. Axons can then send action potential quickly across relatively long distances within the body (from the spinal cord to the toes, for example). Importantly, when myelination occurs, neurons lose some of their flexibility or plasticity. There is a trade-off then between plasticity and efficiency of communication as the brain develops (see Purger et al. 2016). This helps explain the existence of critical and sensitive periods of development since myelination ends the highest levels of plasticity as different brain structures develop. Oligodendrocytes, which are the main glial cells responsible for myelination in the central nervous system, actually suppress subsequent axon growth after a brain structure matures.

In summary, neurons form from multipotent stem cells shortly after conception, proliferate near the early ventricles, migrate and then aggregate to their final locations in the brain. Axons and dendrites develop to allow for action potentials and synaptic communication. Excess neurons and synapses are pruned in a Darwinian fashion and the maturing networks are made more efficient but less plastic by the process of myelination. In the sections that follow, the influence of genetics, experience, diet, and toxins on these stages of brain development are explored. Although a comprehensive review of each of these areas is beyond the scope of this entry, examples are provided of the research that has occurred in each field.

Influence of Genetics, Epigenetics, and Genetic Disorders on Brain Development

It is appropriate to begin any discussion of factors that influence brain development with a section on genetics. Mutations or inherited genetic disorders clearly have a profound impact on the growing brain; yet the more common processes involve the influence of the external environment and

chemicals on gene expression (del Blanco and Barco 2018). The relatively new field of neural epigenetics examines changes in the brain caused by modification in gene expression rather than mutation of the genetic code itself (see Sweatt 2013). Through these processes, evolution, genes, experience, anatomy, and behavior all interact in complex feedforward and feedback directions. Brain development is the result of genetic inheritance that comes through reproductive fitness of the parents. In utero and later environmental exposures and experience influence the expression of the genes to create the anatomy and functioning of the brain at all stages of development. The person then brings this anatomical and functional state to all daily situations that are encountered which results in the behavior expressed. Behavior then feeds back ultimately to reproductive fitness and the cycle continues (Pinel and Barnes 2018).

Genes, the material substance that is passed from parent to offspring, are nucleotide sequences of DNA housed in the nucleus of every cell. Essentially, the expression of a gene results in the production of a protein molecule. These proteins are then incorporated in the membranes and organelles of developing cells. Genes provide a template and the resulting proteins are the active agents in biological development. Thus, genes cannot participate directly in biological processes and do not directly result in different eye color or varied temperaments in a developing child. It is the epigenetic processes associated with expression through protein production that directly alters the makeup and activity of brain cells.

Epigenetic processes result in either increases or decreases in protein production. Two well-known epigenetic mechanisms are histone remodeling and DNA methylation. In histone remodeling, the DNA that makes up the individual genes wrap around a histone protein. When these proteins change shape due to signals related to cell activity or external chemical cues, the DNA that is wrapped around it are also modified (see Bintu et al. 2016). DNA methylation occurs when a methyl group attaches to the gene, usually at a cytosine site, and alters the transcription rate of

the gene (see Schubeler 2012). Regardless of the specific epigenetic mechanism, the key idea is that protein synthesis, and the resultant form and function of brain cells, can be influenced by external factors.

One early and particularly relevant animal example examined the influence of maternal care and early life stress on the neurons of young rats (Weaver et al. 2004). This study found that increased pup licking, grooming, and nursing behavior by rat mothers altered the offspring epigenome (gene expression) at a glucocorticoid receptor (GR) gene promoter in the hippocampus. Pups of mothers with high levels of care were found to have differences in DNA methylation, as compared to offspring of lower care mothers. These differences emerged over the first week of life, were reversed with later exposure to a more caring mother, and persisted into adulthood. Importantly, these changes altered the hypothalamic-pituitary-adrenal (HPA) responses to stress, suggesting a causal relation between epigenomic state, GR expression, and the maternal influence on stress responses in the offspring. Essentially, early stress related to poor maternal care lead to brain changes and a more reactive stress response in adulthood. While human experiments of this type are obviously not possible, these results strongly suggest that brain development can be altered by changes in gene expression based on external factors.

Epigenetic changes influence brain development; yet some of the most devastating effects occur when the genetic code itself is mutated or an abnormal gene is inherited. Usually, the genetic alterations that lead to altered brain development are polygenomic (result of many genes). In these cases, such as most Autism Spectrum Disorders (ASD; see Bourgeron 2015), it is very difficult to discover the direct connections between genetic and brain differences. For ASD, several dozen genes have been implicated with less than 5% of cases being explained by a single gene mutation (Mullins et al. 2016). Although ASD has been associated with developmental changes in the cerebellum, amygdala, frontal cortex, and the fusiform face area, there is little agreement on the

nature of the differences and the specific role of certain genes (Amaral et al. 2008).

There are cases where genetic influences on brain development are better understood. The disorder phenylketonuria (PKU) results from a single gene defect where sufferers lack an important enzyme called phenylalanine hydroxylase. This enzyme, that normally converts phenylalanine into tyrosine, is needed to synthesize the neurotransmitter dopamine. PKU also results in a toxic buildup of phenylalanine in the brain. Children born with PKU quickly develop intellectual delays and suffer from seizures, vomiting, hyperactivity, and brain damage (Strisciuglio and Concolino 2014). The combined effects of a toxic increase in phenylalanine and low dopamine levels leads to increase apoptosis, changes in brain activity, and likely abnormal protein synthesis through epigenetic mechanisms. Thankfully, PKU can now be detected at birth or through methods like amniocentesis so babies can be placed on a diet devoid of phenylalanine (see Casey 2013). This does not eliminate all cognitive effects but does limit the worst symptoms and brain changes. As discussed in the next section, the timing of the dietary changes is important because the brain develops through sensitive periods after which damage can be mostly irreversible (Pinel and Barnes 2018).

Another example of a clear genetic impact on brain development is Down syndrome (see Dekker et al. 2015). In what amounts to a genetic accident, Down syndrome occurs when an extra chromosome 21 is created in the egg during ovulation. When fertilized, the resulting zygote has what is known as a trisomy or three chromosome 21 segments. The result is an overproduction and/or abnormal production of proteins associated with that chromosome. This results in bodily disfigurement, intellectual impairment, and medical complications. At the electron microscopic level, the neurons of individuals with Down syndrome appear to be immature. The dendritic spines in the hippocampus that are normally slender and elongated are seen to be short and stubby (Sylvester 1983). This may partially explain the difficulties these individuals show with learning and memory since the hippocampus is critical

for these processes. It is clear that genetic factors influence brain development but it is also clear that epigenetic changes result from what the child experiences in their everyday lives.

Influence of Experience on Brain Development

In utero, the different phases of neurodevelopment discussed in the first section proceed, for the most part, without the influence of the outside world. During this period, the core components of the nervous system from the spinal cord to the cortical structures of the telencephalon are established. These early events provide the initial arrangement of connections within the brain, and this patterning is both underspecified and plastic at birth. The genetic program of brain development is also staggered so that brain stem structures, those that support basic bodily functions such as breathing, become functional first and certainly before full term birth. Conversely, the neocortex, which processes higher functions like learning and our senses, is still immature and plastic when a child is born (Pinel and Barnes 2018).

Light, sound, specific physical contact, food, and many other sensations begin to be experienced by a newborn. Neurons begin to respond to this sensory input via sensory organs. Those neurons that are active in this new sensory environment tend to add synapses, form networks, and survive while underactive or misplaced neurons are eliminated. As discussed in the last section, this activity also changes the gene expression and leads to altered levels of protein synthesis and growth. Despite rapid growth during the first several years of life (Li et al. 2015), the human brain matures very slowly compared to other animals. As a result, experience has a longer time to impact neural development.

Although clever marketing schemes attempt to convince parents to purchase certain toys or books to properly enrich their newborns, research consistently shows that simply being allowed to interact with other people and the environment is sufficient for normal brain development (Pinel

and Barnes 2018). It is only when extraordinary cases of sensory deprivation and abuse are considered that the impact of experience on brain development can be fully appreciated. One such case involved a young girl known as Genie (Curtiss 1977). She was admitted to hospital at age 13 and was extremely underweight for her age. She could not stand up straight, chew solid food, or control her bladder. Psychologically, she was extremely afraid, could not speak, and made almost no sounds. Genie was the product of unspeakable neglect and abuse from the age of about 20 months until her discovery. She spent her days alone, in the dark and often restrained to a potty chair (see Rymer 1993).

Upon her discovery, great efforts were made to counteract the developmental deprivation she experienced. Initially, rapid improvements were observed. Genie began to walk more normally, make sounds, and say words. Unfortunately, despite this early success, her behavior never became typical. Her speech did not follow grammatical norms and she continued to exhibit silent tantrums among other emotionally dysregulated behaviors. Genie's case is relevant to the important concepts of permissive and instructive experience along with critical and sensitive periods of development (see Assali et al. 2014). Permissive experiences allow genetic programs to be expressed whereas instructive experiences shape the information in the genetic programs and influence the trajectory of neural development. In Genie's case, her genetic complement was ostensibly intact at birth and the normal programs of development were initiated through permissive interactions with the environment. After the 20 months, the amount of external stimuli required for normal development was drastically reduced which had permanent detrimental effects.

The types of experiences needed for normal development are time dependent (Makinodan et al. 2012). Genie passed through several critical periods of brain development without sufficient external stimuli. These critical periods are essential windows of opportunity for stimuli, such as spoken language, to influence the developing brain. Since Genie was not spoken to, read to, or

shown printed words, she was never able to fully acquire these abilities. Sensitive periods occur when it may be optimal but not essential to receive relevant sensory experience. For example, learning a second language may be easier when you are younger (sensitive period) but can be accomplished at any age. Although the term critical period is frequently used, most effects of experience have been shown to occur during sensitive periods (Morishita and Hensch 2008). This finding is important since it suggests that learning and enrichment later in life may be able to counteract earlier missed opportunities.

Environmental enrichment is another important concept related to the influence of experience on brain development. Enrichment can be thought of as the opposite of the deprivation described above. Animal studies have shown that rearing young rats in complex environments leads to larger and more complex brain structures (Greenough 1975). Specifically, studies have found that environmental enrichment in the form of larger cages, toys, and running mazes leads to a thicker neocortex and more synapses per neuron in several brain structures related to learning and memory. Direct observation of these types of microscopic brain changes is obviously not possible in humans but many brain imaging studies have found similar increases in activity following specific forms of enrichment (May 2011). Although it is not possible to directly connect these brain changes to specific enhancements of behavioral ability, it is widely accepted that increased complexity in neuronal circuits suggest increased capacity for learning, sensory sensitivity, and resistance to acquired brain damage in adulthood.

Experience can also influence brain development in more specific ways. Ocular dominance columns form in the developing visual cortex where certain cells respond preferentially to one eye or the other (Hata and Stryker 1994). When the sensory input is altered by blindfolding one eye for a few days early in development, the ocular dominance pattern is altered leading to lifelong detriments in the blindfolded eye. Importantly, this does not occur if both eyes are blindfolded. This confirms that sensory

experience can create a competitive process between inputs to neurons in that functional (active) inputs will take over dysfunctional (non-active) inputs and alter the developmental structure of the brain (Hubel et al. 1977).

Another classic set of experiments in this field investigated the topography of sensory cortical maps. Here, experience in the form of a repeated motor behavior was found to reorganize the activity of the neurons in the motor cortex. When monkeys repeated a novel task, that was similar to a child learning to use a spoon, approximately 700 times, the neural representation of the fingers involved in the task grew in size relative to the unused fingers (Merzenich et al. 1987). This finding, and many other similar results, confirmed that sensory experience can alter the functional neural networks of the brain in lasting ways.

Although the mechanisms that underlie these changes in networks are not fully understood, the basic process has been described. During early development, brain areas are linked to each other through many diverse synaptic connections. Over time, some of these tracts become dominant with larger numbers of synapses but smaller side branches remain. When the behavior of the organism changes or the brain is altered by damage that reduces or eliminates the activity of the dominant connections, the lesser used pathways are strengthened through synaptic plasticity based on increased activity (Borodinsky et al. 2012). At the cellular level, this type of plasticity has been classically described by Donald Hebb (1949). Hebb proposed that when one neuron was involved in activating another neuron through synaptic contact and the second neuron fired an action potential as a result, the connection between the two cells would be strengthened. This is colloquially known as, “neurons that fired together, wire together.” Although this concept is most often used to explaining adult neural plasticity underlying learning and memory, it is obviously also relevant to the development of the brain. Experience is the external driving force that changes neural activity through the sensory systems but other factors such as nutrition and environmental toxins also play a key role in brain development.

Influence of Diet and Environmental Toxins on Brain Development

Optimal brain development involves proper nutrition and low levels of environmental toxins both prenatally by the mother and postnatally by the child (del Blanco and Barco 2018). The developing human body and brain are, however, amazingly resilient to mild alterations in diet and low level of environmental exposure (Garret and Hough 2018). One of the central issues for in utero development is the role of the placental barrier. This semipermeable structure exists between the blood of the mother and the fetus. This structure blocks many large molecules from crossing and therefore protects the developing infant (Blundell et al. 2016). Critical smaller elements and molecules including oxygen and sugars are obviously transported readily across the barrier but this also allows for potentially harmful small molecules such as alcohol and some viruses to directly affect the fetus.

In a comprehensive review, Bolton and Bilbo (2014) examined the brain development of the fetus that resulted from the diet and obesity of the mother. They concluded that maternal obesity and a high-fat diet during gestation/lactation likely “programs” offspring long-term for increased obesity in themselves, along with increased vulnerability to mood disorders. This programming is thought to occur by the perinatal diet propagating inflammation in the brain of the fetus/infant, since obesity and high-fat diets are both associated with exaggerated systemic levels of inflammatory mediators. These immune molecules (e.g., interleukin [IL]-6, IL-1b) are known to play a role in both placental function and brain development. Previous research has shown that any disruption of growth factors or neurotransmitters (e.g., serotonin) by inflammation early in life can permanently alter the trajectory of fetal brain development.

An example with both a dietary and potentially toxic component is the consumption of alcohol by a pregnant mother. Fetal alcohol syndrome (FAS) is a condition that results from sustained level of alcohol consumption at

moderate to high levels during pregnancy (Caputo et al. 2016). This consumption results in a wide range of physical, developmental, and cognitive alterations and deficits in the infant. The brain is the organ most affected in children with FAS. MRI studies show smaller brain volumes in both gray and white matter and alterations in the corpus callosum which is the main communication pathway between the left and right hemispheres of the cortex (Roussotte et al. 2012). Once alcohol crosses the placental barrier, it negatively impacts the development of blood vessels which limits blood flow and the delivery of oxygen to the developing brain (Carmeliet et al. 1996). It also interferes with the migration and aggregation processes outlined above. This leads to increased apoptosis and an underdeveloped brain at birth (Smith et al. 2014).

Environmental toxins are also known to impact brain development. Heavy metals such as mercury and lead can interfere with neuronal activity at the cellular and synaptic level. In their review of this area, Karri et al. (2016) concluded that concurrent exposure of heavy metals, such as lead (Pb), cadmium (Cd), arsenic (As), and methylmercury (MeHg) are particularly harmful due to their long-lasting effects on the brain. These metals all have a binding affinity with NMDA receptors (a receptor for glutamate which is the main excitatory neurotransmitter in the brain), the sodium-potassium pump (which is critical for maintaining the resting potential and resulting action potentials of all neurons), and other cellular processes critical to neuronal function. The presence of these metals interferes with the migration, aggregation, and later functioning of neurons throughout development. Brain abnormalities and varied cognitive deficits related to learning and memory have been consistently observed following heavy metal exposure (Karri et al. 2016). These findings have resulted in the removal of lead from paint and gasoline among other changes.

Psychoactive drugs provide a final example of environmental exposure that is known to alter brain development (Repo et al. 2016). Unlike the earlier examples in this section, this exposure

typically occurs later in development. An example is the use of cannabis by adolescents. Cannabis and its main psychoactive ingredient tetrahydrocannabinol (THC) activate the endogenous endocannabinoid (eCB) system. The eCB system includes two inhibitory presynaptic G-protein coupled receptors, cannabinoid1 (CB1) and cannabinoid2 (CB2). CB1 receptors, which are activated by THC, are expressed throughout the brain in many neuronal populations (Newton et al. 2009). The eCB system regulates the release of neurotransmitters and contributes to long- and short-term synaptic plasticity (see review, Mechoulam and Parker 2012).

Neural structures rich in CB1 receptors such as the amygdala, hippocampus, and the prefrontal cortex in particular are not fully developed in adolescence. The lack of frontal lobe maturity, a structure important for behavioral inhibition and decision-making, is particularly well documented (Pinel and Barnes 2018). Since all of these brain areas are also related to the HPA axis, they are critically involved in the stress response which can be altered by eCB manipulation (Romeo and McEwen 2006). In order to model the scenario where adolescents turn to cannabis to help them cope with stress, Weeks et al. (2015) conducted an animal experiment that placed rats in a stress condition before THC was administered. Once the rats reached adulthood, behavioral testing for fear/anxiety was conducted and brain tissue was processed for synaptic analysis using confocal microscopy. Behavioral results indicated that chronic adolescent THC administration following stress caused adult rats to be more impulsive but not more fearful. Synaptic results indicated significantly fewer synaptic proteins in the lateral amygdala in the stress/THC rats relative to controls. Taken together, these results suggest that preexisting stress followed by THC administration leads to a unique profile of behavioral and synaptic changes. This experiment provides an important example of the continued impact of environmental exposure on brain development into the adolescent phase of development.

Conclusion

The preceding sections described the main phases of brain development and explored examples of factors that are known to influence these processes. The impact of the external environment occurs via epigenetic mechanisms both in utero and after birth. While the discussion focused on earlier phases of development, it is important to acknowledge that the brain continues to develop and change throughout the lifespan. One current controversy related to later development is the topic of adult neurogenesis. Traditionally, the brain was thought to grow rapidly in utero and then more slowly as the child aged. No new neurons were thought to form after late adolescents. That changed when animal studies using birds first identified adult neurogenesis (Goldman and Nottebohm 1983). Since then, evidence has mounted that new neurons form in many species, particularly in more plastic structures such as the hippocampus. This process hypothetically allows these structures to contribute more readily to processes like the formation of new memories that requires higher levels of flexibility. More recent studies have questioned whether this process occurs in humans. One group has found that human hippocampal neurogenesis drops sharply in children to undetectable levels in adults (Sorrells et al. 2018).

Later in the lifespan, brain development is typically defined by a slow rate of neuron loss and typically involves mild cognitive decline (Pinel and Barnes 2018). Researchers looking at this last phase of brain development frequently examine the differences between normal neural decline and more dramatic changes that occur due to disorders like Alzheimer's disease (Rosenberg and Kosslyn 2014). Whereas disease typically creates dementia which is characterized by pronounced memory loss and confusion, normal aging typically involves a decline in fluid intelligence, executive function, and the ability to form new memories (Salthouse 2005). As people live longer and more of the population enters this phase of life, further research in this area will be critical.

The study of brain development continues to present both challenges and opportunities to psychologists seeking to understand the fundamental processes that underlie cognitive development and the neural systems that mediate them. While many fundamental processes have been well defined, the emerging field of neural epigenetics will continue to help us understand the influence of the environment and a person's behavior on the ever changing expression of their individual genome. It is through these complex interactions and feedback loops that we will continue to enhance our understanding of brain development and the factors that influence this critical process.

Definition

Cooking as a potential explanation for the evolution of the disproportionately large human brain.

Introduction

The disproportionately big human brain is a conundrum – it is larger than would be expected for a primate of our size, and it is a very energetically expensive organ. Since human basal metabolic rate (BMR) is not elevated to match such a big brain, the extra energy needed to sustain it suggests a dietary explanation. Feeding the large brain would likely require a shift to a high-quality diet: one comprised of energy-rich, easily digestible foods. This hypothesis is supported by a number of anatomical features: smaller teeth, jaws, stomachs, and a shorter large intestine. Two key elements of human subsistence –

cooking and meat eating – have been proposed as a possible means of achieving this high-quality diet.

Encephalization and Trade-Off Theories

The human line has experienced a remarkable increase in brain size during the last couple of million years: the first major expansion occurred around 2 million years ago (MYA) with the second one following around 800,000 years ago (YA), when the brain increased to its modern level. A modern human's average brain is 4.6 times larger than expected for our body mass and takes up to 20 % of our body's resting metabolic rate (RMR) in comparison to only 9 % for other primates (RMR is conceptually related to the basal metabolic rate, though BMR is more accurately measured). This substantial energetic cost to the body, however, is not accompanied by a corresponding increase in BMR to supply the extra energy, as a mature human's BMR is quite typical of primates. How, then, do humans feed the expanded energy needs of the large brain when the basal metabolic rate remains fixed?

Various theories have been proposed to explain how the expansion of such a costly brain occurred in the human lineage. Aiello and Wheeler's expensive-tissue hypothesis (Aiello and Wheeler 1995) suggests that a size reduction in the gastrointestinal tract (only 60 % of what is expected for a primate our size) energetically balances increases in brain size. The metabolically expensive tissue of the brain is thus offset by a smaller gut – another metabolically costly organ. Such decreased gastrointestinal tract points to diet as a major determinant, with less bulk and higher digestibility of energy-packed foods (e.g., low-fiber plants, fruits, meats) requiring relatively smaller guts. In humans, the colon is only 20 % of the total volume of the digestive tract, compared to 50 % in apes. Since big colons permit fermentation of fibrous low-quality plant foods, humans are relatively poor at utilizing uncooked plant fiber. Aiello and Wheeler propose that cooking – a way to externalize part of the digestive process – might have been an important factor in attaining such a

high-quality diet. The authors' hypothesis of the gut-brain trade-off, however, is challenged by Navarrete et al. (2011), who failed to find the negative correlation between relative brain size and digestive tract for 100 mammal species.

Another theory has been proposed by Fonseca-Azevedo and Herculano-Houzel (2012), who suggest a trade-off between brain size and body size, with larger primates having smaller brains due to caloric restraints that cannot fuel both the brain and body to be large. These caloric restraints are a result of the limited number of hours available for feeding per day and the low caloric yield of raw foods. Their calculations show that, with a raw food diet similar to that of extant nonhuman primates (e.g., great apes), the *Homo* species would have to feed for more than 9 h a day to afford their total body mass and brain size (Cornélio et al. (2016) challenges these calculations, concluding that only 5–6 h of daily foraging would have provided enough energy to sustain a large brain). With this theory of the brain versus body growth trade-off, Fonseca-Azevedo and Herculano-Houzel also point to a high-quality diet as early humans' strategy to circumvent the caloric restraint, with cooking specifically as a way to provide more calories in less feeding time.

Cooking: The Human Universal

The significance of cooking for our biological evolution was not widely discussed until the twentieth century. Because fire was considered to be first controlled by *Homo sapiens*, the origins of cooking were placed only recently – less than 200,000 YA. The shift to a high-quality diet was thus popularly attributed to eating more animal foods. Later archeological evidence gave rise to other approaches, placing cooking as early as 1.8 MYA (around the emergence of *H. erectus*) and increasing academic interest in its role in human evolution. Wrangham's book, *Catching Fire: How Cooking Made Us Human* (2009), supports the earlier adoption of cooking (1.8 MYA) with plenty of time to allow for a larger brain.

Cooking is both a unique and universal human feature: every human culture cooks, while no

other species does. The hypothesis that *Homo erectus* already cooked food by 1.8 MYA is mainly supported by the fact that specific features of *H. erectus* (small mouth, small blunt molars, and smaller gut) are difficult to explain unless a diet of soft easily digested foods was available year-round. In terms of archeological record, there is sparse evidence of fire use as far back as 1 MYA, but it is reasonable to accept its use specifically for cooking after about 800,000 YA. With these timelines we can expect cooking to produce genetic change, considering that other examples of dietary modifications causing genetic adaptations occurred in much less time – such as with dairying and lactase enzyme persistence into adulthood. Indeed, there appears to be genetic evidence for our adaptation to cooked foods (Carmody et al. 2016).

Cooked Starches, Large Brain

Cooking can increase energy gained from food by improving nutrient digestibility, reducing body's costs of digestion, and decreasing the energy spent on immune defenses (by eliminating foodborne pathogens). For humans, the most consistent evidence for cooking's ability to increase net energy gain of food is for starchy vegetables, though there is evidence for meat and nuts as well (► [“Increased Energy/Reduced Digestion”](#)).

Starchy foods in particular could have been important in the evolution of a large brain and particularly in cooked form. The brain tissue is characterized by high glucose demands (the human brain uses up to 60 % of the body's glucose in a resting state), and a consistent diet of cooked starchy plants – the richest form of dietary glucose – can meet such demands quite well. Cooking starches gelatinizes them, allowing the digestive enzyme in our saliva (salivary amylase or AMY1) to begin digesting it. Humans are in fact unusual in the high number of AMY1 genes (six copies, in comparison to only two in other primates), which makes starch digestion more efficient. Hardy et al. (2015) propose that the rapid increase in brain size from the Middle Pleistocene (about 800,000 YA) was energetically affordable due to

the coevolution of cooking and increases in expression of AMY1, as raw starches are poorly digested by this enzyme. While nonthermal methods of food processing, like grinding and blending, can also improve starch digestibility, they cannot achieve the same effectiveness as gelatinization through heat.

Coevolution of cooking and salivary amylase AMY1 would have resulted in higher availability of glucose necessary for the enlarging brain. This is important, because even when the brain uses ketones (by-products of high levels of fat oxidation) during long periods of fasting, its normal functioning still absolutely requires 30–50 g of dietary glycemic carbohydrate per day. One would have to generate large stores of glycogen during periods of sustained fasting, requiring a diet that provides a caloric surplus consistently. The energy expenditure necessary to obtain starchy tubers and roots would have been far lower than that to obtain animal foods for a reliable food source (Carmody et al. 2011).

A Case for Cooking: The Modern Raw Foodist

Some unexpected evidence for the importance of cooking comes from studies with raw food communities. “Raw foodists” are groups living in industrialized societies that avoid cooked foods for perceived health benefits. Studies consistently show insufficient energy on such diets for maintaining body weight (Carmody and Wrangham 2009; Koebnick et al. 1999). In Koebnick et al. (1999), this energy deficiency resulted in 50 % of the female respondents experiencing amenorrhea or the absence of menstruation. These outcomes are surprising, considering that modern raw foodists enjoy access to a rich variety of high-energy foods free of seasonality constraints. In addition, they process their diets quite extensively through dehydration, blending, sprouting, and pickling, which can increase the food's caloric value. Adding cold smoked meats to the raw plant diet did not improve the odds of becoming underweight, so the lack of meat does not appear to hinder

reproductive function or one's energy status. The energy deficiency seen with long-term modern raw foodists, even with the addition of meat, suggests that the diet to which humans are adapted evolutionarily has to include cooked foods.

Nonthermal Processing: An Alternative Hypothesis

Cornelio and colleagues (2016) challenge the hypothesis that cooking is a prerequisite to our brain expansion: they propose that it is the use of tools that helped early hominins increase their daily energetic intake, as well as the inclusion of new food sources – meat and seeds. The author's work with mice indicated no weight gain on a cooked meat diet, suggesting that cooking was not necessary for increasing caloric intake of foods. Not including cooked starches limits the study's conclusions, however, since cooking would be applied to both meat and plants. Carmody et al. (2011) include both foods in their cooked versus raw design and find that mice on cooked meat and plants retain weight, while mice on the raw versions lose it, contrasting Cornelio and colleagues' results. Carmody et al. (2011) also challenge the tool use hypothesis by testing the effect of both cooking and non-thermal food processing methods, such as pounding. They demonstrate that with starches, mice lose weight on the raw diet whether the starchy food is whole or pounded, yet retain weight on the cooked version. With meat, mice lose weight from all versions of the diet but they lose less of it with the cooked meats, again showing higher caloric gain with thermal processing. Therefore, processing methods involving tool use do not appear to match cooking in their ability to increase the net energy value of foods.

Conclusion

According to the archeological record available so far, cooking does not appear to predate the first rapid brain expansion around 1.8 MYA. However, for the second main period of hominin brain

expansion (around 800,000 YA), cooking could have been the crucial element for brain size acceleration by enhancing energy gain from raw foods.

Thermal processing would increase the energy gained from foods, providing the extra calories for an expanding brain. In addition, cooking starchy foods and evolving the extra copies of salivary amylase to efficiently digest them would supply the brain with glucose – its main source of fuel. Nonthermal food processing, such as tool use, could alternatively allow this shift to a high-quality diet. Studies with raw foodists are one challenge to this approach, as even the addition of meat and various processing methods does not improve odds of becoming underweight on an uncooked diet. Another challenge are mice studies that show higher net energy gain from cooked versions of meats and starches than those processed non-thermally. Cooking, thus, is not paralleled by other processing methods and remains an important factor in theories of encephalization.

Definitions

Brain development in the first year refers to normal development of a child's brain in order to achieve developmental milestones.

Introduction

Brain development in a child is a continuous process. It encompasses the neurological and psychological development beginning from fertilization and continues throughout life. Surrounding environment has an impact in overall development of the child. The child's brain develops rapidly in the first year of life, and the child rapidly acquires new skills. The rate of brain growth in the first year is the highest of all succeeding years. The child's brain volume doubles and reaches approximately three-quarters of adult brain volume by the end of the first year. Developmental milestones are also attained expeditiously in the first 12 months. At birth, the human child has very little cortical function, and a child only feeds and sleeps. But at her first birthday, she may walk independently and can typically speak few words.

Embryology of Brain Development

The nervous system develops with formation of a neural tube from the ectoderm. Both ends of the neural tube close by 28 days after fertilization. Once the neural tube is complete, three primary vesicles develop at the cranial end of neural tube to form the brain: *the forebrain vesicle*, *the midbrain vesicle*, and *the hindbrain vesicle* (Snell 2010).

Forebrain (*prosencephalon*) develops from the forebrain vesicle to form cerebral hemispheres (telencephalon) and diencephalon (Fig. 1). Midbrain vesicle forms the midbrain (*mesencephalon*). Hindbrain (rhombencephalon) develops from the hindbrain vesicle to form metencephalon (pons, cerebellum), and myelencephalon (medulla oblongata).

Proliferation of cells in the neural tube around the central canal continues adding to the size and bulk of neural tissue. Progenitor cells in the neural tube differentiate into neurons and neuroglial cells. Each cerebral hemisphere arises by lateral expansion of the forebrain vesicle at the beginning of the fifth week of development. As each cerebral hemisphere rapidly expands, the convolutions form gyri separated by sulci which become

Primary division	Subdivision	Mature structures
Prosencephalon (forebrain)	Telencephalon	Cerebral hemisphere, basal ganglia, hippocampus
	Diencephalon	Thalamus, hypothalamus, pineal body,
Mesencephalon (midbrain)	Mesencephalon (midbrain)	Tectum, tegmentum, crus cerebri
Rhombencephalon (hindbrain)	Metencephalon	Pons, Cerebellum
	Myelencephalon	Medulla oblongata

Brain Growth in the First Year, Fig. 1 Divisions of the developing brain from three primary vesicles. The boxes in the left over the brain corresponds approximate portions of forebrain, midbrain, and hindbrain

Brain Growth in the First Year, Fig. 2 Sequential development of cerebral hemispheres. Brain surface is relatively smooth at 3 months. With rapid increase in cortical surface different lobes with sulci and gyri become prominent gradually

evident on its surface. Up to 3 months of age, the surface of the brain is relatively smooth. Rapid growth of cortical surface through multiple infolding occurs, thereby vastly increasing the surface area of the cortex. Appearance of major fissures occurs in the fifth month. The major fissures include the Sylvian fissure, the central sulcus, the parieto-occipital sulcus, and the calcarine sulcus. The major fissures divide the brain into different lobes. The secondary sulci and the tertiary sulci appear in the seventh to ninth months of gestation, and by birth a child’s brain resembles an adult brain (Fig. 2).

Normal Developmental Process in the First Year

Brain development during the first year of life not only involves an increase in number of brain cells but also forms more connections. Brain

development is a very dynamic process with proliferation of dendritic branches, myelination, pruning of brain cells, and connections that are not being used. The way a child develops from birth to 1 year can be assessed clinically by examining various parameters like head circumference, brain volume, and systematic assessment of developmental milestones (Swaiman 2012). Some of these entities are explained in greater detail below.

Head Circumference

The average head circumference at birth is 33–35 cm. Head circumference is clinically a rough estimate of brain volume and mass. Presence of a microcephaly (small head) or macrocephaly (large head) is abnormal. During the first 3 months of life, head circumference increases approximately at a rate of 2 cm per month. During the period of 3 to 6 months of age, head circumference increases at a rate of 1 cm per month. During the second half of the first year of life, head

circumference increases at a rate of 0.5 cm per month. Together, during the first year, head circumference increases by approximately 11–12 cm.

Brain Volume

The average brain volume at birth is 341 cm³. It is 558 cm³ at 90 days (Knickmeyer et al. 2008). Total brain volume at 2–4 weeks of age is approximately 36% of its adult size. By 1 year, total brain volume reaches 72% of adult brain volume. Increase in brain growth in the first year is 101% from its value at birth. In other words, a baby's *brain doubles* in size over the *first year*. The majority of this growth is in gray matter, with minimal contribution from white matter. Gray matter increases by 149%, while white matter increases by 11%. The cerebellum increases by 240% in the first year which is out of proportion to rest of the brain growth (Knickmeyer et al. 2008).

Biology of Brain Development in the First Year

Neuronal organization, increase in brain volume, differential myelination, dendritic proliferation, newer synaptic contacts, synaptic pruning, and maturation of neuronal transmission continue well after birth and contribute to brain maturation.

Myelination

The process by which axons are covered by an extra layer of fat called myelin begins in the third trimester. In the intrauterine life, brain myelination is restricted to the fibers of the basal ganglia. The brain at birth is largely unmyelinated, and the process of myelination becomes rapid after birth. Myelination insulates certain portions of neurons and makes the neuronal circuit more functionally mature. Myelination of the brain and spinal cord is accomplished by *oligodendrocytes* (a type of glial cell), whereas in peripheral nerves, myelination is carried out by *Schwann cells*. These cells wrap around the axons in multiple layers so that their cell membranes provide sequential layering of lipid around the axon. Myelination of the child's brain progresses rapidly to approach adult pattern by the end of the

second year, though myelination continues at a slower pace far into adulthood.

At birth, human children have little cerebral function. Myelination of different nerve pathways (*tracts*) like corticobulbar, corticospinal, tectospinal, and spinothalamic tracts proceeds in a systematic pattern. The corticospinal fibers complete myelination by the end of the second year.

Dendritic Proliferation

During brain development, nerve cells sprout branches that form new connections from one cell to many others. In the newborn there are fewer axons, and their organization is very much simple with relatively few connections. As the child ages, the axons and dendrites profusely branch (*arborization*) to form multiple connections (Kolb and Fantie 1989). Dendritic proliferation and new synaptic contacts followed by differential myelination make the electrical circuits of the brain more efficient.

Pruning

During the process of brain development, cellular proliferation occurs, creating excess neurons and glial cells. A large number of these cells are programmed to die. Pruning refers to the process of dying off of brain cells and elimination of connections that are not used or are harmful. Pruning increase the efficiency of neuronal transmission.

Glial Development

Gradual proliferation, maturation, and organization of glial cells are important for efficient and effective neuronal function and metabolism. The glial cells in the central nervous system are *oligodendrocytes*, *astrocytes*, *ependymocytes*, and *microglia*. Oligodendrocytes myelinate the nerve fibers in the central nervous system. Due to multiple processes, a single oligodendrocyte can form as many as 60 internodal segments in axons of multiple neurons. Astrocytes provide supporting framework, limit spread of neurotransmitters, store glycogen, and produce trophic substances and growth factors. Ependymal cells form a single layer of cells around the ventricles and the central canal of the spinal cord. They possess microvilli

and cilia which help in the flow of the cerebrospinal fluid. Microglia may be inactive in a normal brain, although some current research suggests they may help to fine-tune neuronal circuits and assist with synaptic and structural plasticity. They proliferate in disease and inflammatory conditions and help in phagocytosis.

Imaging Studies of Brain Development

MRI techniques provide excellent anatomical resolution to study the human brain development in infancy. Studies have shown that gray matter volume increases significantly more than white matter volume during the first year of life (Knickmeyer et al. 2008). Gray matter volume begins to decline, and white matter volume begins increasing at 6–7 years and continues through adolescence. The decline in gray matter may be associated with synaptic pruning and cortical maturation (Gogtay et al. 2004).

18-FDG positron-emission tomography (PET) studies have shown that in infants below 5 weeks of age, utilization of glucose is maximized in the sensory and motor cortex. This is in concordance with the fact that these areas are clinically and physiologically the most mature areas at birth. Brain metabolism in other areas increases gradually. By 8–9 months, there is evidence of active metabolism of glucose throughout the cortex (Chugani and Phelps 1986).

Primitive Reflexes and Disappearing Signs

A newborn is born with a unique set of reflexes (Kliegman et al. 2016) that are present either at birth or in the following few months. They gradually disappear around 1 year of age (Amiel-Tison and Grenier 1986). Their persistence beyond certain ages is of pathologic significance and indicates impaired brain development. As cerebral function matures, the primitive reflexes gradually disappear due to suppression by the matured brain. In some of the central nervous system diseases, these reflexes reappear in adulthood due to

loss of cortical function. Reappearance of primitive reflexes in adulthood is pathological signs of lobar dysfunction (lobar release signs):

1. Moro reflex

When a baby is held suspended in supine position with the examiners hands supporting her back and head, and when the head is dropped back a few centimeters, there is rapid abduction of the arms, hip flexion, and leg extension. This sign is present in all full-term newborns. This is usually lost at 4–5 months of age. The center for this reflex is thought to be present in the lower pons and medulla.

2. Tonic neck reflex/fencing posture

In supine position, when the baby's head is turned to one side, the arm and leg to which side the head is turned are extended, while the opposite arm and leg are flexed. This reflex is present at 1 month of age and disappears by 6 months. Persistence of obligate tonic neck reflex is indicative of asymmetric CNS development and predicts choreoathetoid cerebral palsy.

3. Crossed adductor reflex

This reflex consists of contraction of bilateral hip adductors when either knee jerk is elicited. It is present at birth and disappears by 7–8 months of age. Its persistence beyond this period is suggestive of early corticospinal tract lesion.

4. Other pyramidal signs

While eliciting plantar reflex, the baby's knee is flexed, and the thigh is externally rotated. In this position, the outer aspect of the sole is firmly scratched with a blunt point such as a key. The direction of scratching then turns inward toward the middle of metatarsophalangeal joint. A normal response in adults consists of flexion of the metacarpophalangeal joint of the great toe and flexion of the other toes. An abnormal response in adults involves great toe extension and fanning of the other toes, suggesting pyramidal tract lesion and is known as positive Babinski sign. A positive Babinski sign is considered normal in children up to the age of 1 year.

5. Grasp reflex

This reflex is elicited by stroking the palm of the child with a finger, to which the baby usually grasps the finger. This is present in all term newborns and disappears by 4 to 5 months of age.

6. Parachute reflex

When a baby is held in horizontal position with face downward and is then thrust downward, she extends her arms to break the fall. This is well developed by 6 to 7 months of age.

7. Rooting reflex

By lightly touching the corner of the lip of the baby, there is sucking movement of lips with deviation of mouth in the direction of the stimuli. This reflex disappears by 3 to 4 months of age. This reflex helps the baby find the breast to begin feeding.

8. Sucking reflex

By lightly touching the center of the lip, sucking movement of lips occurs. This reflex develops in the 32nd week of pregnancy and is fully developed at term. Premature babies may have a weak sucking reflex and difficulty in feeding.

using the limbs and trunk like neck holding, rolling over, sitting, and standing.

Language Development

Language is one of the most critical parts of child development. It helps the child to communicate and helps in developing relationships. There are two main areas of language: *receptive language* and *expressive language*. Receptive language refers to understanding and comprehension of language. Expressive language is the use of language through speech to communicate needs, thoughts, and ideas. Development of language is dependent on both *perceptual abilities*, such as ability to hear and understand sound and on *motor control* of larynx, lips, palate, tongue, and muscles of facial expression.

Social and Cognitive Development

Social and cognitive development plays an important role in emotional development of the child and prepares the child to act and respond to different social situations. Children become aware of their surrounding and understand their needs, desires, and feelings. These skills help them to judge others' behavior and to engage with others in a meaningful way (Table 1).

Postnatal Developmental Milestones During the First Year

Developmental milestones are a set of physical or behavioral signs of development and age-specific tasks that most children can do at a certain age. There are different domains of child development such as motor development, language development, and social and cognitive development.

Motor Development

Motor skills are the movement that occurs when the nervous system and muscles work together which are intended for various purposeful activities. Motor skills generally fall within two types: *gross motor* and *fine motor*. Fine motor skills refers to small movements of fingers, toes, and wrists to fulfil tasks like picking up a small object with the hand, holding a rattle, or lifting a spoon from the floor. Gross motor skills are larger movement

Conclusion

The rate of brain growth in the first year is the highest of all succeeding years. The child's brain volume doubles and reaches approximately three fourth of adult brain volume by the end of the first year. Gray matter volume increases significantly more than white matter volume during the first year of a child. At birth, human child has very little cortical function and motor functionalities such as sucking and swallowing which are essentially reflex in nature. Many primitive reflexes appear during infancy and gradually disappear as the brain matures. Increase in brain volume, myelination of nerve fibers, dendritic proliferation, synaptic pruning, neuroglial organization, and maturation of neuronal transmission continues after birth and contributes to brain maturation and efficient brain function. A child must achieve certain

Brain Growth in the First Year, Table 1 Key developmental milestones in the first year (Kliegman et al. 2016; Swaiman 2012; Kolb and Fantie 1989; Amiel-Tison and Gosselin 2001; Illingworth 1987)

Age in months	Gross motor	Fine motor	Language	Social and cognitive
1	Turns head when supine Chin up when prone	Infantile grasping	Makes sounds other than crying Startles to loud noise	Gazes at bright objects Regards mother's face Comforted by sound of human voice
2	Extends and turns neck in prone position Tries to steady head briefly when held	Hands unfisted 50% Retains rattle if placed in hand	Coos Social smile	Follows large objects with contrast Recognizes mother Responds to adult voice and smiles
3	Keeps head above horizontal for longer periods Rolls to side	Inspects fingers Bats at objects	Chuckles Babbling Vocalizes when talked to	Reaches for parent's face
4	Sits with trunk support Pulls to sit with no head lag Rolls front to back	Clutches objects and clothes Plays with rattle	Laughs aloud Vocalizes when alone Localizes to sounds Varies pitch of vocalizations	Selective attention to parents faces
5	Sits with pelvic support Moves back to front	Grasps cube using whole hand (palmar grasp) Transfers object: hand-mouth-hand	Expresses anger with sounds other than crying	Recognizes caregiver Forms attachment to caregiver
6	Sits momentarily Pivots in prone on belly Exerts weight on forearms in prone position	Transfers hand-hand Grasp objects with both hands	Listens and vocalizes Smiles and vocalizes at mirror	Removes cloth on face Bangs and shakes toys
7	Sits without support (steady)	Grasps using side of hand (radial-palmar grasp)	Increasing variety of syllables	Explores different aspects of a toy
8	Gets into sitting Pulls to sitting/kneeling	Grasps with all four fingers and side of thumb (scissor grasp) Takes cube out of cup	Says "Mama" (non-specific) Imitates sounds	Let parents know her mood Seeks object after it falls to the ground
9	Begins creeping Crawls	Thumb-forefinger grasp Bangs two cubes together	Orients to name well	Uses sounds to seek attention Separation anxiety Social gestures
10	Creeps well Stands with one hand held Walks with support of two hands held	Isolates index finger and pokes	Says "Dada" (specific) Waves "bye-bye"	Uncovers toy under cloth Learns fear Gives attention when name is called
11	Walks with support of one hand held Pivots in sitting Stands few seconds	Throws objects Stirs with spoon	Says first word Vocalizes to songs	Looks at pictures in book

(continued)

Brain Growth in the First Year, Table 1 (continued)

Age in months	Gross motor	Fine motor	Language	Social and cognitive
12	Stands well with arms high and legs splayed Independent steps	Fine pincer grasp of small objects Can hold a pencil Towers two cubes	Uses several gestures with vocalizing Vocabulary of 5–10 words	Opens lid of a box to find objects Kiss on request

Definitions

Brain imaging is the use of modern technology to study structural anatomy, physiology, and metabolism of brain.

Introduction

The evolution of modern brain imaging is synchronous with medical imaging with the discovery of X-ray in 1895 by German physicist Wilhelm Roentgen. It started with plain radiography of skull in different views and progressed with discovery of contrast agents and modification of X-ray technique for image acquisition. Radiographs taken after in vivo introduction of various contrast agents lead to development of pneumoencephalography, ventriculography, and

angiography. Modification of X-ray technique with continuous stream of X-rays collected on an input screen after passing target organ allowed real time visualization of moving anatomical structures like a video called *fluoroscopy*.

The introduction of *Ultrasound*, *Computed Tomography*, and *Magnetic Resonance Imaging* revolutionized medical imaging in terms of resolution, spatial, and three dimensional imaging. With digital revolution, images can be obtained quickly and downloaded onto a computer and multiple modification, subtraction, and 3D reconstruction can be carried out. Ultrasonography and Magnetic Resonance Imaging are unique in the sense that they do not expose patient to ionizing radiation like X-ray.

In addition to structural imaging of cranial cavity and brain, functional imaging of brain and study of cerebral metabolism is now possible with advancement of MRI techniques and Nuclear Medicine Imaging. Nuclear Medicine Imaging expose patients to radiation but unlike X-ray the source of radiation in these modalities are radioactive substances (radioisotopes/radionuclides).

History of Brain Imaging

Wilhelm Roentgen in 1895 used the X-rays to produce the first ever plain radiographic image of his wife's hand. Since then radiograph of every body part was taken including that of skull and cranial cavity. In brain imaging air was the first contrast media introduced in vivo. *Ventriculography* and *Pneumoencephalography* are the first contrast radiographic techniques using air discovered by American neurosurgeon Walter Dandy (1886–1946) in 1918. He introduced ventriculography by injecting air to the lateral ventricle of brain via a surgically created burr hole and then took radiographs of head. In Pneumoencephalography he introduced air into subarachnoid space around the brain via a lumbar drain placed invasively in the midline of lower back. Ventriculography and Pneumoencephalography are highly invasive diagnostic procedures and with availability of newer and safer imaging modalities these are no more used and are the things of past (Kornienko and Pronin 2009).

A more useful contrast radiography that revolutionized the diagnosis and therapeutic intervention of vascular brain diseases is *Cerebral Angiography* introduced by Portuguese neurologist Egas Moniz (1874–1955) in 1927. He used intra-arterial radiopaque dyes as contrast media to highlight brain vasculature in radiographs.

The invention of *Computed tomography (CT)* in 1970s was a milestone in medical imaging and provided instant detailed anatomic images of brain in multiple sections noninvasively and revolutionized not only emergency management of head injury and neurologic emergencies but also neuroscience research. Allan McLeod Cormack and Godfrey Newbold Hounsfield shared Nobel Prize for Physiology or Medicine in 1979 for the invention of Computed tomography.

Nuclear magnetic resonance imaging was used in 1940s to determine the structure of complex molecules. Its application in medical imaging was developed gradually with contributions by many researchers. Peter Mansfield and Paul Lauterbur received the Nobel Prize for Physiology or Medicine in 2003 for their contribution to MR imaging. Over the last 30 years MRI techniques have undergone tremendous refinements providing excellent internal architecture of brain and have dominated the field of functional imaging (Raichle 2009).

Concurrently with development of CT and MRI in the early 1980s, the development of safer bio-compatible radio-isotopes and gamma cameras leads to introduction of nuclear medicine imaging and allowed positron emission tomography (PET) and single photon emission computed tomography (SPECT) for functional imaging of the brain.

Conventional and Contrast Radiography

X-rays are a form of electromagnetic radiation and are generated from a cathode ray tube. As the X-rays pass through the body, they are differentially absorbed and attenuated by tissues depending on its density. After passing through the body it interacts with the photographic film. Simply said, X-rays blackens the photographic film.

In the body, air attenuates X-rays a little. So the body part containing air allows the X-rays to pass with little absorption and blackens the photo film maximally. The order of attenuation power in body tissues is as follows: **Bone** > **water** > **fat** > **Air**. Bone attenuates X-rays the most and after passing bony tissue, little X-ray is available to interact with photographic film. Hence, bone appears white in X-ray film (Armstrong and Wastie 2001).

As a result of revolution in digital technology, images can be loaded onto computer screens quickly and print outs can be taken (if needed) without need for darkroom procedure to develop photographic film.

Modifications to this X-ray technique and availability of intravascular contrast agents allow a continuous stream of X-rays to be digitally collected on a computer to allow real-time visualization of moving anatomical structures in fluoroscopy and angiography.

During angiography it is often difficult to visualize the contrast agent passing in the blood vessels with the overlying bony structures. That problem is circumvented with the advent of computers and softwares that digitally silence the signals from bony structures making excellent visualization of blood vessels as in digital subtraction angiography of cerebral vessels.

Ultrasonography

Ultrasound is a high frequency sound wave produced by piezoelectric materials. The sound waves travel through the body and bounce back from the internal organs. The piezoelectric material also receives the sound waves and the signals are interpreted by a computer to generate a real-time image on the display (Armstrong and Wastie 2001).

Though ultrasonography is the second most commonly performed imaging modality in medicine, its use in brain imaging is limited. It is used for brain imaging of infants to avoid radiation exposure and due to presence of fontanelles in infants it provide good acoustic windows for brain imaging. Another use of ultrasound techniques is Doppler ultrasound that enables

determination of blood flow, direction, and velocity within a vessel. So transcranial Doppler is frequently used in clinical practice and in research to study flow dynamics in major cerebral blood vessels.

Computed Tomography (CT Scan)

CT scanner obtains a series of images of the body in the axial plane with a rotating gantry containing the X-ray tube and detectors, which revolve around the patient. The signals are digitally processed to construct a two-dimensional grey-scale cross sectional image of a body slice. As CT is based on attenuation principle of X-rays, the image follows the same order of attenuation power in body tissues. However, CT has a far higher contrast resolution allowing the assessment of tissues with minor differences in attenuation characteristics.

Modern multidetector CT machines allow movement of the patient's table along with patients body during the gantry revolution, thus speeding up the image acquisition process greatly reducing the scan time to seconds for a typical brain scan. It is also possible to reformat the image in different planes with help of computers. With thinner collimation, better spatial resolution, and improved computer technology, it is possible to reconstruct three-dimensional images of specific tissues like bone windows or 3D reconstruction of skullbase and facial skeleton. CT angiography of cerebral vessels and 3D rendering of vessels is also possible (Fig. 1).

Magnetic Resonance Imaging (MRI)

Magnetic resonance imaging is based on the spin properties of proton in the presence of a strong magnetic field. Water is present in all biological tissues and the protons within the hydrogen nuclei of water are regarded as magnetic dipoles randomly oriented in space. In the presence of a magnetic field as within a MRI scanner, the magnetic dipoles are aligned with the magnetic field. On applying a brief pulse of radio waves, the

Brain Imaging, Fig. 1 CT Scan of head and brain with different reconstructions. (a) shows axial scan of brain parenchyma. (b) is a axial bone window with brain parenchyma

silenced. (c) represents a 3D reconstruction of facial skeleton. (d) and (e) are CT angiogram of cerebral blood vessels in lateral and antero-posterior views, respectively

dipoles absorb energy and deflected. When the radiofrequency pulse is removed, the dipoles emit small radio pulse signals and re-align themselves (relax). These signals are digitally processed and spatially encoded in a powerful computer to construct an image. The signals produced depend upon the properties of different tissues and the manner and rate of relaxation of the hydrogen nuclei. By altering the scanning parameters like the time between radiofrequency pulses (*Time to Repetition*) and the time between radiofrequency pulse and signal reception (*Time to Echo*), two types of relaxation can be measured: the T1 and T2 relaxation times. Accordingly T1-weighted images and T2-weighted images can be obtained (Adam et al. 2014).

The T1-weighted images of brain show fluid such as cerebrospinal fluid (CSF) as black (dark) and fat as white (bright). T2-weighted images of

brain show a bright signal from cerebrospinal fluid and a darker signal from fat. Gadolinium forms the basis of intravenous MRI contrast agent which reduces the T1 and T2 relaxation times resulting in a high signal on T1-weighted images. MRI also takes into account the physiologic and dynamic processes in the brain at molecular level such as Brownian movement of molecules and flow related diffusion effects to produce image contrast (Fig. 2).

The advantages of MR imaging include excellent spatial and contrast resolution of soft tissues, multiplanar imaging, and absence of ionizing radiation. Advanced MRI sequences can also be used to assess flow within vessels to produce angiograms of cerebral blood vessels. MRI imaging is advancing rapidly with availability of newer sequences so that each sequence can highlight a specific anatomic or functional area within brain

B

Brain Imaging, Fig. 2 T1 and T2 MRI sequences of brain. (a) and (b) represents T1 and T2 axial images of brain, respectively. (c) and (d) represents T1 and T2 sagittal images of brain, respectively

like nerve fiber tracts, CSF spaces, early ischemic changes, brain edema, and functional imaging associated with neural activity (Armstrong and Wastie 2001).

The main safety issues in MRI are presence of powerful magnetic field, possibility of contrast reaction, and long time taken for scanning. Strong magnetic field can make metallic objects to become dangerous projectiles and can dislodge MRI incompatible implants, devices, or foreign bodies. So MRI is contraindicated in persons with ocular metallic foreign bodies, cardiac pacemakers, cochlear implants, aneurysm clips, etc. MRI takes long time for image acquisition and patients require to be co-operative and still within the scanner. So

scanning is difficult for persons with pain or irritability or anxiety and for babies who may need general anesthesia. The advantages and disadvantages of MR imaging are summarized in Table 1.

Functional magnetic resonance imaging (fMRI) uses the different magnetic properties of oxygenated and deoxygenated hemoglobin to look for blood flow patterns in different areas of the brain in relation to performance of different thought, perception, or physical activity. With a specific action related to thinking, perception, speech, or motor activity, the area in the brain responsible for that function gets activated and blood flow to that area increases. The changes in flow patterns are detected in fMRI to reveal specific

Brain Imaging, Table 1 Pros and cons of commonly used modalities in brain imaging

	Conventional radiography	Ultrasound	CT Scan	MRI	Nuclear medicine
Pros	Easy to obtain	No radiation exposure	High spatial and tissue resolution	No radiation exposure	Functional imaging and study of cerebral metabolism possible
	Very low cost	Portable to bedside	Contrast resolution enhanced by intravenous contrast agents	Extremely good soft-tissue resolution	Imaging of the whole body possible
	Real time imaging possible with fluoroscopy	Very low cost	Very fast image acquisition	Contrast resolution enhanced by intravenous contrast agents	PET scanning is valuable in diagnosis of metastatic Brain tumors and study of metabolic disorders
		Good soft-tissue resolution	3-dimensional and multiplanar reconstruction possible: 3D image of skull and cranial cavity, CT angiography	Imaging technique of choice for brain pathologies like tumors, stroke, epilepsy.	
		Good for assessment of ventricle size in infants due to presence of fontanelles	Imaging of choice for head injury and neurologic emergencies	Functional imaging possible	
		Doppler studies allow study of cerebral blood flow dynamics		Safe in pregnancy	
Cons	Radiation exposure	Limited use in brain imaging	Very high radiation exposure	Contraindicated for ocular metallic foreign bodies, Pacemakers, Cochlear implants, aneurysm clips	High radiation exposure and needs handling of radio-isotopes
	No cross sectional/spatial image	High inter observer variability	Poor brain resolution compared to MRI	Claustrophobia	Poor contrast and spatial resolution
	Poor soft tissue resolution	Images cannot be reliably reviewed once imaging is over	Relatively contraindicated in pregnancy due to risk of radiation	Long time taken for image acquisition so patients requires to be still, making it difficult in children who may need anesthesia	Often nonspecific and confounding
				Expensive and availability is limited	

brain areas. The subjects are presented with visual, auditory, and sensory stimuli or asked to perform some simple motor tasks while within the MRI scanner. fMRI can reveal brain areas activated

with these processes. The major applications of fMRI other than research are localization of motor strips, localization of speech areas, and identification of memory laterality in the temporal lobe

for neurosurgical planning (Logothetis 2008). Due to absence of radiation, high spatial resolution, and moderately high temporal resolution, fMRI is replacing PET for functional brain imaging (Detre and Floyd 2001).

Nuclear Medicine Imaging

Nuclear medicine imaging provides not only anatomical image of the brain but also functional and metabolic information. For this the patient is given intravenously a special radiopharmaceutical containing a radioisotope that emits gamma rays. Depending on the absorption, distribution, and extent metabolism of the radiopharmaceutical in the body, differential amount of gamma rays are emitted by different body parts. Gamma rays are detected using a gamma camera and images are obtained. The most commonly used radiopharmaceutical contains technetium 99 m as Gamma rays emitter. It scans the whole body and used in detection of occult metastasis anywhere including skull and brain as metabolic hotspots because cancer tissues increasingly take up the radiopharmaceutical and emit maximum Gamma rays (Elgazzar 2011).

Two extensions of Nuclear medicine imaging which are more relevant for both anatomic and functional imaging of brain are *positron emission tomography* (PET) and *single-photon emission computed tomography* (SPECT).

Positron emission tomography (PET) is an imaging technique which detects positron emitted from radionuclides. A positron is an antielectron, which is positively charged. The most commonly used PET radionuclide is 18-fluorodeoxyglucose (FDG) with fluorine 18 as positron emitter. Tissues that are actively metabolizing glucose take up this compound and show up as a hot spot. PET is extremely useful for functional brain imaging. On performance of different thought, perception or physical activity specific brain areas are metabolically activated and utilize more glucose so that the areas can be identified. Instead of glucose 18-fluorine can be tagged to other ligands to map different aspects of neurotransmitter activity and to study different metabolic diseases of brain. For

example, 18-fluoro-6-L-dopa when injected to body, distribution of dopaminergic neurons in brain can be studied. PET is useful to identify primary cancer site when patient presents with a brain metastasis with unknown primary. It is also used for the assessment of response to treatment and recurrence of tumor.

SPECT uses gamma ray emitting radionuclides which is rapidly taken up by the brain. This involves cerebral blood flow imaging using a “SPECT agent” (e.g., Technetium-99 m hexamethylpropyleneamine oxime) which is rapidly uptaken by brain without redistribution. A common use of SPECT is to localize the site of seizure onset when anatomic imaging is nondiagnostic. During seizure SPECT will identify focal hyperperfusion and in the interval between seizures it will identify focal hypoperfusion in the area of brain responsible for seizure onset.

Magnetoencephalogram

Magnetoencephalogram (MEG) measures magnetic fields of brain. Magnetic field is produced when electrical current flows inside neurons of cortical gray matter of brain. Magnetic field is perpendicular to the direction of intracellular currents in neurons. Whereas electroencephalogram (EEG) measures the electrical current via scalp electrodes, magnetoencephalogram (MEG) measures magnetic fields of brain by extremely sensitive devices. For Magnetoencephalogram, subjects are not placed inside a magnetic field as in MRI. Rather magnetic field detectors are placed around patients head to measure the magnetic fields produced by the brain. Magnetoencephalography is used for identifying the origin of cortical seizure (epileptogenic focus) and in presurgical mapping of eloquent cortex. MEG directly measures the electrophysiological changes in brain. So it has higher temporal resolution compared to fMRI. fMRI detects changes in regional blood flow and oxygen use by hemoglobin to assess functional activity of brain which is slower than electromagnetic activity detected by MEG.

Advantages and Disadvantages of Different Brain Imaging Modalities

The CT scan and MRI constitutes the bulk of brain imaging ordered in hospitals now a days. The advantages and disadvantages of commonly used modalities in brain imaging are summarized in Table 1.

Conclusion

Both structural and functional imaging of brain is now possible with an array of imaging modalities. Though CT and MR imaging constitute the major bulk of brain imaging modalities presently performed in a clinical setup, other techniques have their due share in medicine and research. Conventional radiography, CT scan, and nuclear medicine imaging expose patients to ionizing radiation in varying proportions and must be performed appropriately. The risk of such examinations has to be weighed against the benefit to the patient in terms of increased diagnostic yield and techniques that do not use ionizing radiation, such as ultrasound and MRI, should be carefully considered as alternatives, particularly in children and pregnant women (Royal College of Radiologists 2017).

Synonyms

[Brain mapping studies](#); [Brain structure-function mapping](#)

Definition

Studies of brain anatomical-physiological relationships that focus on investigating the physical or cognitive effects of clearly delineated lesions, i.e., damage to tissue from disease, injury, or malformation.

Introduction

Some of the earliest brain lesion studies were done in subjects with a specific impairment, usually of language, and were mapped to the relevant region of damage via postmortem studies. Modern brain lesion studies, which investigate a range of functional impairments, including language, motor, and cognition, usually rely on in vivo

neuroimaging to detect, quantify, and map brain lesions to their associated impairments.

Historical Brain Lesion Studies

One of the first examples of a brain lesion study was in the famous patient nicknamed “Tan,” as this was the only word this patient was able to say. This patient, Louis Victor Leborgne, suffered from epilepsy and, as it was discovered after his death via an autopsy performed by Paul Broca in 1861, a lesion in the posterior inferior frontal gyrus. This area roughly corresponds to Brodmann’s areas 44 and 45 and is also known as Broca’s area. This is one of the first examples of mapping a highly circumscribed lesion location in the brain to a very specific function, i.e., language production. Others were to follow. In 1874, Karl Wernicke identified regions at the temporal and parietal lobe boundary that, when lesioned, would result in the patient having fluent but disordered speech. One other famous example of lesion studies is the famous case of Henry Molaison, who suffered from epilepsy and had surgical resection of the anterior two thirds of his hippocampi, parahippocampal cortices, entorhinal cortices, puriform cortices, and amygdala (Scoville and Milner 1957). His case played an important role in the understanding of brain anatomy and the formation of memories, and his brain anatomy was made publicly available after his death in 2008 (Annese et al. 2014).

Modern Brain Lesion Studies

Modern brain lesion studies focus on relating quantitative neuroimaging metrics to related impairments. One main analysis method is that of voxel-lesion symptom mapping (VLSM) that relates brain anatomical lesions to specific physical or cognitive impairment on a voxel-wise basis (Bates et al. 2003). Recent advances in functional MRI and diffusion MRI, which allow quantification of the anatomical and physiological connections in the brain, have been used to

investigate the network effects of lesions. Some recent examples are those that quantified the functional (Boes et al. 2015; Sutterer et al. 2016) and structural connections (Kuceyeski et al. 2015, 2016) that were disrupted due to a particular lesion, which then allowed for further insight into the integrated, network effects of a primary lesion area.

Simulated Brain Lesions

Noninvasive brain stimulation techniques, e.g., transcranial magnetic stimulation (TMS), allow for modulation of neuronal activation in highly circumscribed areas of the cortex that is transient in nature. Recent studies using repetitive TMS investigate the use of so-called transient “virtual” lesions in the brains of healthy controls to map particular area(s) and networks in the brain to cognitive or physical impairments or enhancements (Pascual-Leone 1999). For example, one recent study showed enhanced visual-spatial attention resulting from a virtual lesion in the parietal cortex (Hilgetag et al. 2001), while another showed deficits in complex motor sequence processing after virtual lesions of Brodmann’s area 45 (Clerget et al. 2013).

Conclusion

Brain lesion studies have historically and in modern times allowed for a clearer understanding of the relationship between anatomical regions of the brain and associated functions. Modern neuroimaging and simulated lesion studies are being used to not only understand the effect of the primary area of the lesion but also the effect of the lesion on the functional and structural network connections in the brain.

Definition

The intelligence of an animal is related to the external and intrinsic properties of the brain which determine its functions.

Introduction

To the common observer, it would seem obvious that animals differ in their intelligence and that human intelligence, at least from our own biased perspective, is far superior to that of other animals. But what exactly is animal intelligence and how is it linked to the parameters of the brain?

Knowledge on animal intelligence is not only of interest to comparative ecologists, evolutionary psychologists, and neuroscientists, but it is also important to the general public as this helps shape public perception regarding welfare, care, and use of animals.

What Is Animal Intelligence?

One of the major obstacles in comparing intelligence across species remains the acceptance of a universally accepted definition of intelligence and how to measure it. In humans, intelligence is usually defined as: “... *a general capability that, among other things, involves the ability to reason, plan, solve problems, think abstractly, comprehend complex ideas, learn quickly and learn from experience. It is not merely book learning, a narrow academic skill, or test taking smarts. Rather, it reflects a broader and deeper capability for comprehending our surroundings- ‘catching on’, ‘making sense’ of things, or ‘figuring out’ what to do*” (Gottfredson 1997). In other words, human intelligence is the sum effect of our mental capacities which includes our abilities to communicate, think abstractly, and reason. Human intelligence is thus readily assessed using established intelligence tests (Intelligence Quotients, IQ tests) which, although challenged on the basis of their application across cultures, have proven to be fairly robust instruments for assessing verbal, numerical, or visual-spatial reasoning in humans. However, this same definition of intelligence cannot be directly applied to the study of nonhuman animals and thus a broader definition of animal intelligence is defined as the ability of an animal to be able to solve problems occurring in their natural environments (i.e., the degree of behavioral flexibility) (Roth and Dicke 2005). Examples of this include naturally occurring challengers such as locating food sources, intraspecific communication and social interactions with conspecifics, as well as spatial orientation (Dicke and Roth 2016). Using behavioral flexibility as the central measure for comparison, cross-species investigations have revealed that the evolution of intelligence is not unique to

humans but has evolved independently in several groups of animals, including certain insect, mollusk, bird, and mammalian species (Butler and Hodos 2005).

Absolute and Relative Brain Size

When comparing brains across species it is tempting to think of large brained animals as being more intelligent than smaller brained species and that intelligence is simply a result of absolute differences in brain size. Not surprisingly, when one compares absolute brain size across mammals, the human brain is far surpassed by that of large bodied terrestrial and aquatic mammals like the elephant and the blue whale. For example, the human brain weighs approximately 1350 grams while the elephant brain weighs more than 5 kg (Maseko et al. 2011) and that of the blue whale (the largest aquatic mammal) weighs in excess of 7 kg. At face value, this would lead one to believe that elephants and whales are far superior to humans in intelligence, but this conclusion is unlikely given that whales have fairly simple neocortices (Striedter 2005), and that there exists no behavioral data to support this argument. Similarly, larger bodied artiodactyls (e.g., ox, giraffe, camel) outstrip many nonhuman primates in terms of absolute brain size, even though monkeys and apes in particular are well known for their complex behavioral repertoire, cognition, and flexibility (Jolly 1966). These observations point to the fact that simple comparisons of absolute brain size across species are rather misleading and that absolute brain size does not align with our observations of animal intelligence across species.

Another approach which has been used to compare brains across species has been to evaluate relative brain size (i.e., relative to body size) using either brain:body mass ratios or allometric plots of brain size against body size. When comparing brain:body mass ratios, the human brain is calculated as occupying 2% of total body mass, whereas the fraction of body mass dedicated to brain mass in the blue whale is only 0.01% of its total body mass (Striedter 2005). While

these observations align with our expectations of greater intelligence in humans relative to whales, comparisons of small bodied species such as the shrew (van Dongen 1998) and harvest mouse (van Shaik 2006) suggest otherwise as these species have brain:body mass ratios larger than humans (between 4% and 10% of their total body mass). To address this problem, comparative biologists have also compared species brain:body mass data using allometry to evaluate proportional changes in brain size across species. This approach allows one to remove the influence of body size in species comparisons and identify species which have brains that are larger (or smaller) than expected for their body size. When brain mass is plotted against body mass for all the major vertebrate groups (i.e., mammals, birds, reptiles, amphibians, and fish), the distribution of data points aligns relatively well with the behavioral complexity observed across species. Mammals tend to have larger relative brain sizes than birds, while reptiles and amphibians have larger brain sizes than most fish but smaller brain sizes than birds (Jerison 1973). Humans also have relative brain sizes which far exceed that of other animals (Manger et al. 2012).

Brain Complexity and Intelligence

While the use of allometry has seemingly reaffirmed our expectations of how differences in brain size align with comparisons of animal intelligence it is important to keep in mind that brain size and brain complexity are not one in the same thing and may change independently of one another. For instance, a species could increase its cognitive output (i.e., intelligence) relative to that of an ancestral species by changing the complexity of the brain while still maintaining (or even reducing) brain size in the descendent species. To borrow an example from the technological industry, the transition from bulky early cellular phones to that of present day smart phones was facilitated by increasing the processing power of the individual components and reducing their overall size. In a similar way, changes in brain complexity might

constitute a myriad of changes in the intrinsic properties of the brain (e.g., changes in the size of its subcomponents, changes in the number or diversity of its cellular components, changes in the degree of compartmentalization, changes in the number or diversity of synaptic or neurotransmitter components, etc.).

Some of the most striking observations of neural complexity have been found within the nervous systems of small brained invertebrates like the arthropods. For instance, while insects are endowed with a more distributed, simple nervous system, they also possess a component of the nervous system known as the mushroom bodies which underlie the cognitive and social behavior of insects (Heisenberg 2003; Perez-Orive et al. 2002; Farris 2008). Comparative studies have revealed that the mushroom bodies have undergone changes in complexity in several different insects including the Lepidoptera (butterflies), Blattoidea (cockroaches), and Hymenoptera (i.e., bees and wasps). For example, in bees the mushroom bodies are relatively enlarged (Strausfeld 2012) and are composed of calyces which differ from the smooth mushroom body surface observed in other insects and are convoluted, a pattern similar to what has happened to the increased folding of the mammalian cortical surface (Farris et al. 2004). The possession of complex mushroom bodies in insects has been shown to be associated with a high degree of behavioral flexibility, allowing insects like the honeybee to do complex navigational feats as well as elaborate social, communicative, and learning behavior (De Marco and Menzel 2005).

Further examples of changes in nervous system complexity and associated changes in intelligence are also seen within the molluscs. While most molluscs have fairly simple nervous systems, the cephalopods are an exception having developed large, complex brains and an intriguing set of complex behaviors (Moroz 2009). For example, the nervous system of the octopus is the largest among all the invertebrates and is compartmentalized into 16 lobes (Nixon and Young 2003; Roth 2015) with the vertical lobe being identified as the major control center for complex

behavior (Hochner et al. 2006). The complexity of the vertical lobe in the octopus aligns well with the range of complex behavior observed for this animal, with octopi reported to have a capacity for observational learning (Fiorito and Scotto 1992). While fish intelligence is rarely considered a point of discussion, perhaps because fish remain one of the major food sources for human consumption (Brown 2015), there are certain teleost fish which demonstrate cognitive abilities which cause us to question our a priori assertions of fish intelligence. For instance, cichlids are known to use both visual and auditory cues in the context of caring for the brood, as well as complex appeasement behavior when interacting with individuals of a higher social rank (Bshary et al. 2002). This data seems to warrant further study of the cichlid nervous system and the underlying brain regions that might mediate this complex behavior. Comparative studies of the teleost nervous system have revealed evidence that brain region size can vary in a mosaic fashion. For instance, in comparison to other closely related fish, the cyprinids (goldfish and carp) have large vagal lobes which are used for taste and food processing while catfish have evolved a unique lobe for taking in electro-sensory information from their barbels (Striedter 2005).

While the avian brain is markedly different in structure from that of mammals (most notably the absence of the six-layered lamina arrangement and a clear white matter-grey matter distinction), the expansion of the telencephalon and pallium is also believed to underlie complex behavior within birds, much like it functions for mammals (Striedter 2005). A subregion of the avian pallium is thought to be functionally equivalent to the mammalian dorsolateral prefrontal cortex (Gunturkun 2005), which in humans is involved in executive functions such as planning, cognitive flexibility, and abstract reasoning. Observations of complex behaviors in certain birds (parrots and crows) have added credence to this idea. For example, several studies have demonstrated the remarkable abilities of crows to make and use tools (Hunt et al. 2007), while magpies are also known to recognize themselves

in mirrors (Prior et al. 2008), an observation which had previously only been observed in great apes, elephants, and dolphins (although see Manger 2013 for a criticism of this analysis). In primates, as with other mammals, intelligence has been closely linked with the expansion of the prefrontal cortex (Duncan et al. 2000). In this regard, nonhuman primates are known to possess a number of complex abilities including tool usage (Kendal et al. 2010), imitation (Call et al. 2004), mirror self-recognition (Gallup 1970), and theory of mind (Povinelli et al. 1990; Tomasello et al. 2003) all of which highlight the existence of high intelligence despite brain sizes much reduced in size in comparison to that of humans (e.g., the chimpanzee brain weighs about 350 grams, four times smaller than that of the human).

These observations highlight the cooccurrence of biological complexity and intelligence in the brains of various animals and emphasize that the evolution of intelligence is not unique to humans. The exact selection pressures which favored the coevolution of complexity and intelligence in animals remain a source of ongoing debate. Among others, the importance of sociality and social learning as a driving force for overall intelligence has at least helped to explain the cooccurrence of brain complexity and intelligence in social species like primates (Whiten and van Schaik 2007; van Schaik and Burkart 2011).

Conclusion

The study of animal intelligence in a comparative context has revealed that brain size as well as brain complexity are two important considerations when trying to understand the underlying neural correlates of intelligence and the evolutionary factors which facilitated the emergence of complex behavior.

Brain Size Growth in Humans and Nonhuman Primates

Big brain evolution; Human brain size evolution; Primate brain size evolution

Definition

Increase in brain size found in humans and other primates over evolutionary time.

Introduction

Primates' brains are considerably larger than most other species. Big brains are uncommon because they require a large amount of energy. Possibly, because of this constraint, brain size is related to the diet of the species (Allman 1999). There is a large developmental period for human infants in order to accommodate brain size growth. The social nature of primates has led to the suggestion that a potential reason for this size increase is the necessity for social intelligence (Humphrey 1976).

Brain Size Differences

Brain size is highly correlated with body size. As body size increases, the brain increases exponentially at a rate of around 0.74 for non-primates and 0.75 for primates. Although this rate is about the same, primates have brains around 2.3 times the size of non-primates (Allman 1999). Brain size is commonly compared across species using the encephalization quotient (EQ), which is the ratio of actual brain weight to expected brain weight. Humans have an EQ of about 6.3 (Jerison 1973). It is possible to trace the change of brain size in

hominids over evolutionary time (Tobias 1987). The early hominids, australopithecines, had brains only slightly larger than the chimpanzee. If the EQ of ancestral hominin species is expressed as a percentage to that of *Homo sapiens*, then *Australopithecus afarensis* had an EQ of 41% of *Homo sapiens*, *Homo habilis* 53%, and *Homo erectus* 72%.

Brain Development

The growth of primate brains has led to an increase in cranial size. Because of bipedal locomotion, there is an evolutionary trade-off between a mother's hip size and birth size in human infants. It is suggested that humans have adapted to this restraint by continuing brain development after birth. It is estimated that approximately half of all synaptic connections are made after birth (Changeux 2004). At the time of birth, 40,000 connections are made per second (Bourgeois 1997). This dendritic growth, synapse formation, and myelination require a large amount of energy. Two-thirds of the resting metabolism in newborn babies is allocated for brain growth and functioning, which is half of the energy used by chimpanzees (Bogin 2000). Because of this extended period of development, human infants require much more parental care after birth than do other primates.

Brain Size and Diet

When the brain size among primates is plotted on a linear regression as a function of body size, the variation can be accounted for by diet (Allman 1999). Fruit-eating primates have been found to have larger brains than leaf-eating primates. This trend has also been found in other species such as bats and parrots. It is theorized that because there is an energy trade-off between the digestive organs and the brain, the easy digestibility of fruit enables increased energy flow to the brain. Fruits have a higher energy content than leaves but are more difficult to obtain. Spread over large areas, gathering fruit requires a larger amount of

spatial navigation than gathering leaves and a greater amount of temporal judgment because fruits are harvested at different times of the year. Limited availability may also result in an intense competition with other animals (Allman 1999). Differentiating between types of fruits and identifying ripeness require a color vision system, which has been shown to relate to larger neocortex sizes (Barton 1998).

Brain Size and Intelligence

There is a correlation between brain size and behavioral capacity, so it was first proposed that the EQ was a measure of intelligence (Lashley 1949). Measuring the relationship between brain size and intelligence led to the discovery that it is possible to predict brain density and the relative size of individual structures from overall brain size (Jerison 1973). The additive hypothesis theorizes that because the brain is shaped as a result of different selection pressures, some areas develop specialized neural systems over evolutionary time. These specific areas increase in size, rather than the entire brain increasing as a whole. This is supported by the rate of brain size increase across species (Jerison 1973). The evolution of the complex visual system characteristic of primates is suggested to be a large contributor to this size increase.

Intelligence is often defined as a creative behavior modification in response to the external world (Humphrey 1976). Primates have demonstrated great intellectual abilities in laboratory settings, but their environment rarely necessitates such abilities. The social situation found in primates allows for information transfer between individuals, and much of daily survival relies on subsistence technology rather than individual creativity. From this, it seems that primates have greater intelligence than what is needed to survive. The social intelligence hypothesis posits that the high intellect of primates is necessary for social processes (Humphrey 1976). Social interaction requires an intricate analysis of behavior. Anticipating the actions of others, determining appropriate responses, weighing rewards and

consequences of actions, and deciphering social cues are all necessary skills. Social interaction is viewed as a subjective transaction. Primates who live in larger groups have a larger neocortex size compared to the rest of the brain (Dunbar 2004). However, not all species who live in larger social groups have a larger brain compared to other species.

Conclusion

Compared to most animals, primates have an exceedingly large and costly brain. They make up for this energy requirement by diet changes, such as the consumption of fruit and meat (Allman 1999). Human birth occurs earlier development because the expansion of skull sizes can cause birth complications. This results in an increased duration of infant development and parental care. The most prominent explanation for this increase in brain size is the social intelligence hypothesis, which theorizes that social cooperation requires complex cognition (Humphrey 1976).

Feeding milk to offspring from mother's breast

Introduction

An important distinction of mammals from other animal groups is their ability to produce milk to feed their offspring from the mammary gland. The word mammal is derived from the Latin word “mammilla,” which translates to breast. One would have assumed that Carolus Linnaeus, the father of taxonomy who named the different classes of animals, would have chosen a name for mammals that was inclusive of both the males and females. Perhaps something to do with the other distinguishing features of mammals such as hair and sweat glands. However, Carolus Linnaeus allegedly chose the word mammal to depict the importance of offspring feeding from their own mothers' milk (Schiebinger 1993). Although other animals can also feed their offspring through body secretions (e.g., crop milk in various bird species; Eraud et al. 2008) they do not contain nearly the same rich and varied nutrients as mammalian milk produced in glands that are as specialized for feeding offspring (McClellan et al. 2008).

Evolution of Breastfeeding

Indeed, breastfeeding is arguably one of the most important developments of the mammalian species. Breastfeeding may have evolved approximately 200 million years ago (mya) even before other distinct mammalian characteristics such as hair/fur (Sanchez et al. 2013). There are about 4000 species of mammals today that inhabit a wide range of environments from the Antarctic seas to Australian deserts (McClellan et al. 2008; Pond 1984). One important reason that mammals are able to survive in diverse environments is their ability to lactate which helps feed their offspring and keep their offspring alive. This investment in offspring represents a divergent evolutionary step towards a slower life history strategy for mammals than for virtually all other animals (Hrady 1999). For example, female brown bears (*Ursus arctos*) can lactate even while estivating (similar to hibernating) for an entire season. Similarly, female baleen whales (*Balaena*

australis) can be starved for many months and still have the ability to lactate. These patterns across mammals suggest that breastfeeding likely initially evolved as mechanism for parents to feed offspring when food sources were scarce or varied (Pond 1997; Sellen 2007). Not to mention it was also a strategic way to utilize the body fat and nutrients already stored in mothers (Sellen 2007). Milk allows for infants to consume nutrients from the environment that have already been processed (i.e., obtained and safely digested) by their mothers (Boyd 1998). Thus lactation represents a very focused, yet malleable, form of parental investment that likely offered mammals a competitive advantage over other animals.

Breastmilk is made from important nutrients in the mother's bloodstream and body fat storage and consists of various nutrients including protein, fat, and sugar. These nutrients are essential for the growth and development of the infant (Rollins et al. 2016). More specifically, contents in mammalian milk help to provide the nutrients necessary for development of infants' immune system. Infants' immune systems across different mammals are significantly underdeveloped at birth and therefore require an extensive amount of metabolic energy to develop and maintain (Goldman 2012). By receiving these resources from mothers' milk the infant can direct other nutrients and energy toward the growth of important body parts, such as the heart, brain, and lungs.

What's more, lactation and the contents in breastmilk change as the infants' immune system develops. For example, human breastmilk starts off as colostrum, which is a very concentrated milk with many nutrients while still being easily digestible for infants (Ballard and Morrow 2013). Colostrum plays an important role in forming a protective layer in infants' gastrointestinal tracts and protecting infants from foreign pathogens. Colostrum then turns into more mature milk called foremilk (approximately 3–4 days after the birth of the infant) which is relatively less concentrated and contains various proteins and vitamins essential for the continued growth of the infant. Finally, foremilk turns into hindmilk during the course of feeding, increasing the caloric richness of the milk (Ballard and Morrow

2013). Such changes in breastmilk over the course of feeding and/or with the development of the infant are also found in other mammals (e.g., Hinde et al. 2009). At the more extreme end, mothers can terminate this costly investment in offspring by either refusing to nurse, or stopping production of milk (Hrdy 1999). Thus there is a great deal of flexibility in nursing that can allow mothers to tailor their parental investment according to individual and environmental circumstances.

Another adaptive factor that likely contributed to the use of breastmilk is the ability to protect the infant from pathogens. By triggering various biochemical reactions, the enzymes and hormones in breastmilk help newborns transition from a life in the uterus, which is a relatively sterile environment, to life in the outside world, which consists of various pathogens and bacteria (Colen and Ramey 2014). For example, enzymes in breastmilk, such as lysozyme, help destroy bacteria in the infant's digestive track (Ballard and Morrow 2013). Additionally, leukocytes (a type of white blood cell) in breastmilk directly help fight infections, which allows the infant to become immune to substances in the environment without developing any infections or inflammations (Ballard and Morrow 2013). Thus breastmilk may play a pivotal role in the success of mammalian immune systems, effectively giving them the capacity for the biochemical and/or epigenetic expression of immune responses from one generation to the next.

Additional to the nutritional and protective benefits of breastmilk, breastfeeding may have also helped offspring to be dependent on their mothers (Pond 1997). This was presumably essential for parents to ensure that infants receive nourishment regardless of the resources in the environment as well as the indirect benefit of ensuring the infant is close by in order to protect the infant. These factors would have been important to ensure infants' survival and consequently help to increase parents' evolutionary fitness. Lactation was also likely instrumental in spacing births of subsequent offspring, giving mothers yet another means with which to modulate their reproductive investment (Sellen 2007). Although

the actual mechanism of how this works is not yet completely understood, the frequency of infants' suckling is shown to be a key component in delaying mothers' sexual cycle (Stewart 1988). This would have been an important adaptation especially in species where infants are developmentally delayed (e.g., slow to acquire motor skills) and require high levels of parental investment, as is the case in primates, so that parents' investment is not spread thin by feeding and investing in several highly dependent offspring.

Variation of Breastfeeding in Animals

The contents of breastmilk across mammals share many similar components. For example, most mammalian milk share structural similarities and similar sequences of antibodies (Acharya et al. 1994; see above). Additionally, most mammals show compensatory milk growth in which animals can increase their milk supply when more than one infant is nursing at the same time as well as make metabolic adaptations during lactation (McClellan et al. 2008; Sellen 2007). Closely related species therefore produce similar breastmilk contents likely because they evolved in similar environments within similar time frames. For example, components of milk that contribute to the development of the immune system in human infants is most similar to a closely related primate, chimpanzees (*Pan troglodytes*; Goldman et al. 1998). Additionally, an antigen-binding component in human milk that protects against the α -galactosyl epitope is also found in apes and Old World monkeys but not in New World monkeys and other types of mammals, which are more distant relatives of humans compared to apes and Old World monkeys (Goldman et al. 1998).

However, there are specific components in the milk within each mammalian species that differ from the other species (Goldman 2012). Various factors may have influenced these species-specific differences. One such factor may be the result of differences in the duration of lactation. For example, baleen whales lactate for five to seven months (during which the mothers usually fast) and

produce milk with high energy outputs. In contrast, dolphins (*Tursiops truncatus*) lactate for one to 3 years (during which the mothers frequently feed) and produce milk with relatively less energy output (Ofstedal 1997). Baleen whales therefore have relatively less time to produce milk so it is beneficial for them to make less milk but compensate for the low quantity with high energy milk, whereas dolphins have more time to produce more milk and therefore would not need to produce milk with very high energy. This balance of the caloric content versus nursing duration appears to allow mammals to tailor their maternal investment to species, or even individual-specific, feeding and life strategies (Boyd 1998). For example, due to the threat of unstable pack ice, hooded seals (*Cystophora cristata*) nurse their infant pups for a remarkably brief duration of only 4 days (Boyd 1998)!

Another reason may be differences in the development of each species. For example, human and cow (*Bos taurus*) milk differ drastically in the number of antibodies such as immunoglobulin G (IgG; protects against bacterial and viral infections; Yolken et al. 1992). Newborn calves naturally have less IgGs levels but receive IgGs from the mother's colostrum (the first phase of breastmilk; see above) which consists of high levels of IgGs. Newborn calves therefore attain adequate amount of IgGs after the first nursing. On the other hand, human newborns also do not produce IgG but they receive it quite immediately from mothers through the placenta at birth. As a result, human milk did not require to make high levels of IgGs as seen in cow milk. Another example is that human newborns can survive without breastmilk for a few days with other supplements (although this is not recommended; World Health Organization 2009) but this is not the case for piglets (*Sus scrofa domestica*). This is likely because human infants have relatively higher levels of fat (about 10%) compared to piglets (about 2%) which allows human infants to sustain themselves for short periods of time (McClellan et al. 2008).

Finally, breastmilk content may also be influenced by the type of environment that the animal inhabits because milk may be able to

compensate for the lack of nutrients in the environment. For example, one experimental study showed that cows that were given grain supplements had lower milk fat concentration compared to cows that were only pasture fed (Reis and Combs 2000). This is likely because the former group of cows did not need to expend bodily resources to make high fat content milk.

Primate Breastfeeding

Unlike other mammals, primates do not seem to fit the earlier discussed breastfeeding patterns such as producing volume and quality of milk relative to body size or exposure to pathogens (Ofstedal 1984). Unlike other mammals in which milk content is analogous to body size, the milk composition in primates is relatively lower in nutrients (fat, protein, and energy) but high in lactose relative to their body size. This may be because primates' breastmilk have evolved with relatively lower reproductive rates and slower life history strategies (compared to their relative body size e.g., Hinde 2009). This is a parsimonious explanation because the relatively lower protein concentration in primate milk fits with the slow growth rate of primate infants (Sellen 2007). Additionally, the low fat concentration found in primate milk likely coevolved with continuous infant carrying whereas the high levels of lactose may have coevolved with faster postnatal brain growth in primate infants (Sellen 2007). Furthermore, there are individual variations in milk composition between mothers based on number of offspring they have had as well as the sex of their offspring (Hinde 2009; Hinde et al. 2009).

Another important exception to primates is that breastfeeding is not as "automatic" as it is with other mammals (Volk 2009). Despite primate infants' natural suckling reflex similar to other mammals, female primates require a period of learning in order to be able to successfully nurse their infants. Studies show that monkeys are less likely to be able to successfully nurse if they have not observed another monkey nurse or if they have not nursed before themselves (Volk 2009). Additionally, multiparous primate mothers

(mothers who have previously had other offspring) are more successful at nursing compared to primiparas mothers (first time mothers; Volk 2009). Researchers have suggested that this dependence on learning to breastfeed may be associated with primate species' level of intelligence (Volk 2009). For example, great apes are more intelligent compared to other primates and therefore require relatively more learning in order to successfully breastfeed. Hrdy (1999) has proposed that this learning may be a trade-off between the reliability of innate behaviors and the flexible power of a learning brain.

How Is Human Breastfeeding Different?

Humans are the primate species that is both least dependent on instinctive behavior patterns and least successful at automatically achieving nursing success (Volk 2009). Although infants possess an instinctive rooting reflex associated with nursing, it is clear that other behavioral aspects of breast feeding are not innate for either the mother or the infant. A review of captive great ape nursing showed technique-based failure rates of 18%, whereas human mothers in Western cultures reported failure rates of up to 33% due to technique problems (Volk 2009, 2002). Thus, this fundamental feature of mammalian life does not appear to be either automatic or instinctive for many human mother-infant pairs. Some of the difficulties in initiating and continuing breastfeed that are reported by women include: difficulties initiating and maintaining an appropriate "latch" (i.e., mouth to nipple contact), an inadequate volume of milk expressed by the breast, and/or cracked and/or bleeding nipples (Volk 2009).

This is perplexing when put into the context of how important successful breastfeeding would have been for the survival of human species. Throughout human history our very diverse palates and environmental choices likely meant that infants regularly encountered changing and limited dietary sources. Therefore, lactation and ability to breastfeed would have been crucial for helping infant humans to survive. Even as humans began industrialization and agriculture to serve as

their food supply the associated new pathogens and bacteria they would have introduced during such developments would have made the immunological benefits of human breastmilk very important for infant survival. Infants who are breastfed also appear to enjoy later advantages in health and mental acuity (Rollins et al. 2016). What's more, women appear to be adapted to breastfeed (or at least receive benefits from it). Women who breastfeed for 12 months or longer have their risk of ovarian and breast cancers, as well as Type 2 diabetes, reduced by almost a third (Chowdhury et al. 2015). Thus (as in the animal literature mentioned above), breastfeeding appears to offer human mothers and infants significant survival advantages, making it a prime candidate for strong evolutionary selective pressure.

So why are rates of breastfeeding so unsuccessful for women and how did women overcome this important challenge to infant and mother survival? Volk (2009) suggests three reasons. First, an emphasis on learned versus instinctive behavior may put humans at a relative disadvantage. A second related reason may be that due to infants' delay in motor development compared to other primates, they require mothers' help to successfully breastfeed, such as requiring assistance with inserting the breast far enough into the infants' mouth to allow for sufficient milk flow (Volk 2009). A third reason may be the shape and size of women's breast (Volk 2009). In comparison to body size, humans have the largest breast size of all primates. This likely occurred as a result of evolutionary sexual signaling (Volk 2009). This may have made it challenging for human infants to nurse because it may have required relatively more complex physical and/or oral movements on behalf of the infant to successfully breastfeed (Volk 2009).

Social Factors that Assist Women's Breastfeeding

Women's challenges with breastfeeding therefore appear to represent a significant evolutionary problem. If one-third of mothers have

difficulty feeding their infants, and infants required breastmilk for survival (prior to the invention of formula), one would have expected natural selection to strongly select for maternal and infant characteristics that improved the success of nursing. That natural selection hasn't done so suggests that learned technique may not have been a serious problem for ancestral women. But why?

One plausible answer is that women coped with the challenges of breastfeeding by living in cooperative communities with other mothers who could teach and assist new mothers in learning how to breastfeed their infants (Volk 2009). This simple solution does indeed appear to work exceptionally well. In less developed countries where formula is scarce, over 98% of women successfully breastfeed their infants (Houston 1981). This is typically done in the complete absence of government and/or health care interventions. Young girls can observe their mothers, aunts, and neighbours nurse their infants. When women give birth, they can receive assistance and advice with breastfeeding from other more experienced women. Such social bonds may have also been beneficial for maternal and infant care (Hrady 1999). The recognition of the importance of this form of learning has led to the various modern-day interventions such as hospital programs, professional midwives, the La Leche League, lactation consultants, and parenting workshops that are each dedicated to giving mothers support, encouragement, and the knowledge necessary to successfully breastfeed (Fletcher and Harris 2000).

Additionally, women's partners are shown to be an important support system that has a significant influence on breastfeeding success. Studies show that women who perceived their partner to favour breastfeeding were more likely to continue breastfeeding than women who perceived their partner to favour bottle feeding or did not show preference for breastfeeding method (Scott and Colin 2002). Women's partners who do not favour breastfeeding are most likely to discontinue breastfeeding. Other factors that contribute to women's decisions to breastfeed include women's level of education and beliefs in the value of breastfeeding (Rollins et al. 2016).

Human social communities may have also benefitted women who were completely unable to breastfeed. Historically, and also in some societies today, women who cannot breastfeed their infants for various reasons can receive the help of other women, known as wet-nurses, to breastfeed their children. These practices date back to at least to Roman culture and can even be found in ancient mythologies and biblical stories (Fildes 1988). This was common practice in upper-class families that consisted of biological mothers who were unable to or preferred not to nurse their infants (Fildes 1988). This is another potential form of parental care since wealthy mothers use their resources to “buy” nutrition for their offspring, allowing them to direct more resources towards other offspring and/or somatic maintenance. Similar practices can still be found in some developing countries and are termed “milk kinship” (Altorki 1980). This is typically when more than one woman breastfeeds a child. In addition to helping the survival of the infant, milk kinship can also create social bonds across different communities and classes. For example, children who have been nursed by the same woman are known as milk-siblings and considered to be equal to biological siblings in social standing. However, it remains unknown whether children who are exposed to different breastfeeders may develop higher levels of immunocompetence as a result of their exposure to the antibodies of more than one mother.

Benefits of Breastfeeding

Clearly humans may have derived characteristics of lactation from ancestral mammals and share many similar features of lactation with nonhuman primates. The persistence of breastfeeding through evolutionary history is put into perspective when you consider other changes across human evolution including transitioning from walking on four legs to two legs, increased brain size, and changes in dental structure. This suggests that the functions of breastfeeding (e.g., contents in the breastmilk and how infants digest the milk) have stayed consistent over the evolution of humans with great evolutionary benefits (Sellen 2007). Humans,

similar to other mammals, have also developed the ability to breastfeed regardless of any modest changes to their body conditions. However, although women may still be able to lactate despite slight shifts in their maternal condition, such as modest levels of exercise and/or moderate weight loss (Sellen 2007), there may be a lower limit in how much nutrition the body needs in order to produce quality breastmilk. For example, severe environmental challenges may indeed affect the quantity of breastmilk and the mother's health given the significant metabolic costs of producing milk (Monnier et al. 2015). Therefore, maternal health during and post-pregnancy is imperative for both mother and infant health.

Today, the World Health Organization recommends that infants should be breastfed within one hour of birth and the recommended duration of breastfeeding is for the first 2 years of the infants' life (World Health Organization 2009). Indeed, the benefits of breastfeeding are now widely recognized within the pediatric literature (Gartner et al. 2005). The death of thousands of children around the world can be prevented each year with increased breastfeeding practices (World Health Organization 2009). Human infants who do not receive breastmilk are more likely to die before they reach 1 year compared to infants that are (either partially or completely breastfed). However, complete breastfeeding appears to be optimal as the risk of dying due to diarrhea and other infections decreases when infants are completely breastfed (World Health Organization 2009).

In addition to helping infant growth and protecting infants against infections, breastfeeding is also shown to influence infants' circadian rhythm (Sanchez et al. 2013). The last stage of breast milk, mature milk, when given to the infant the same day it is expressed is shown to influence infants' sleep-wake cycle which benefits the infants' functioning and synchronizations of body systems. Breastfeeding can also result in higher IQ and health later in childhood (Rollins et al. 2016). Infants' behaviour of waking at night to breastfeed is also suggested to be an adaptation to extend mothers' lactational amenorrhea (via further increasing maternal fatigue/load and reduction in the hypothalamic-pituitary-ovarian

axis recovery, therefore serving as contraceptives) which may delay the time for mothers to be able to have the next child (Hrdy 1999). This increases the infants' chance of survival by reducing the possibility of a future sibling.

Breastfeeding also has various benefits for the mother. The hormones released during breastfeeding help to strengthen the mother-child bond by increasing levels of Oxytocin in mother (Rollins et al. 2016). Additionally, breastfeeding is associated with lower rates of breast cancer. One of the reasons for this is that breastfeeding may help temporarily drain the breasts of potential chemical carcinogens. As well, increase oxytocin from breastfeeding may inhibit cell proliferation and tumor growth. Additionally, lactation may reduce cholesterol levels in the breast. Moreover, in modern society, breastfeeding is also economically cheaper compared to buying infant formula (Rollins et al. 2016). Finally, breastfeeding is shown to reduced birth intervals. This is likely because when reducing the frequency of breastfeeding increases the return of ovarian cycling and therefore reduces maternal depletion (Sellen 2007).

Conclusion

Understanding breastfeeding across evolutionary history sheds light onto how adaptive this behavior may have been for various species of mammals. The fact that this behaviour appears unchanged across human evolution despite all the other changes humans have endured attests to how important breastfeeding is for human development. Unfortunately, aside from the physical limitations that women already have to endure to facilitate breastfeeding, there are various social factors that still continue to impede women's decisions to breastfeed. One of the most relevant of those factors today is mothers having to decide between breastfeeding and returning to work. Various women report that returning to work post-partum can hinder their milk supply and therefore choose not to breastfeed at all (Rollins et al. 2016). However, there appears to be slight rise in employers accommodating mothers who breastfeed as it benefits the employers by

increasing female employee's health, attendance, productivity, and satisfaction. More prevalent accommodations for mothers in the work place is still warranted. Global economic estimates suggest that "not breastfeeding is associated with lower intelligence and economic losses of about \$ 302 billion annually or 0.49% of world gross national income" (Rollins et al. 2016, p. 491). Thus there are significant incentives for promoting breastfeeding when it is possible and productive to do so. This is reflected in the enshrinement of breastfeeding and its advantages as part of the UN Convention of Rights of the Child.

Yet while most pediatricians surveyed report an increased awareness of the importance of breastfeeding, they also report lower success rates and less confidence in the costs/benefit ratio of breastfeeding for mothers (Feldman-Winter et al. 2017; attitudes measured in 1995 compared to 2014). Therefore, we suggest that it is imperative that women should be given the necessary information, tools, and support to help facilitate this very important behavior. As noted in our review, and by leading pediatricians (Rollins et al. 2016), breastfeeding is an issue that goes beyond mothers and infants to involve extended support networks that involve many others. At the same time, we recognize that there are cases where breastfeeding remains an elusive and/or impossible task, and in such cases concur with pediatricians that a healthy and happy mother/father/caregiver-infant relationship is quite possible via the use of formula (Feldman-Winter et al. 2017). While women should be informed and supported, they should not be bullied or belittled based on their breastfeeding performance (or lack thereof). Regardless of whether an infant is fed formula or breastmilk, the most important nourishment may very well come from a loving, caring relationship with their parental caregiver.

Breast Feeding and Mother-Infant Attachment

John R. Britton

St. Joseph Hospital, Denver, CO, USA

Definition

Breast feeding is the feeding of breast milk to the infant.

Attachment is the emotional tie that develops from the infant to the parent.

Introduction

Breastfeeding has been shown to have positive effects upon health and nutrition of infants and has been associated with increased educational achievement and cognitive ability in childhood (Oddy et al. 2004). It is also believed to foster development of the maternal-child relationship. Studies of the association of breastfeeding with this relationship have used a variety of constructs that assess the interaction of the mother and child at different stages of child development (Kielbratoowska et al. 2015). However, the developing maternal-child relationship in early childhood is perhaps most frequently characterized by the concept of infant-maternal attachment (Ainsworth 1989), abnormal development of which is thought to predispose to many aspects of later psychosocial pathology.

Background

Attachment was first described by Bowlby, who theorized that infant behavior is adapted to complement caregiver behavior when the caregiver's behavior is appropriate and responsive to the infant's cues (Bowlby 1969). The term "attachment" refers to the tie from infant to parent and is a representation of "the internal organization of the individual" (Ainsworth 1989). A child whose mental representation of the parent as available and responsive is likely to be securely attached to the parent. When such a representation is lacking, insecure attachment occurs. For the securely attached infant, the parent provides a secure base from which to explore the environment.

A basic component of attachment theory is that infants gradually develop a relationship with a principal attachment figure and that the attachment figure's sensitivity to the infant's needs may be a critical factor for the establishment of a secure attachment (Bowlby 1969). Several decades of research (DeWolff and van Ijzendoorn 1997) have established that sensitivity is an important but not exclusive predictor of secure attachment. The exact definition of sensitivity has varied widely in attachment research, yet promptness, consistency, and appropriateness are thought to be main constituents of this construct (Shin et al. 2008).

Although Bowlby's theory acknowledged that feeding may facilitate maternal-infant proximity and thereby provide opportunity for sensitive interaction, his clinical observations led to predictions that neither feeding itself nor individual differences in feeding, such as breast or bottle, contribute to individual differences in attachment quality (Cassidy and Shaver 1999). Recently, however, several studies have suggested a possible link between breastfeeding and attachment, and these studies will be reviewed in this chapter.

The literature on breastfeeding and attachment has come from the fields of medicine, nursing, and psychology. Accordingly, PubMed, PsychINFO, CINAHL, and Embase were searched for 40 years for the following search terms: breastfeeding, sensitivity, attachment, infant-mother attachment, mother-infant relationship, bonding, kangaroo

mother care. The search yielded no randomized trials addressing the relationship of breastfeeding to either attachment or sensitivity; therefore, a meta-analysis was not possible. Although there were numerous studies on sensitivity and its possible relationship to breastfeeding, only five empirical studies addressed the relationship between breastfeeding and attachment. As a result, these formed the focus of the present review (Table 1).

These studies varied with respect to design and construct measurement. Perhaps most consistently measured was attachment security, which is measured after the child reaches 1 year of age most frequently using the Strange Situation Procedure, the Attachment Q-Sort, or the Toddler Attachment Sort (Cassidy and Shaver 1999), although other measures have been used (Tryphonopoulos et al. 2014). On the other hand, there is no generally accepted method of measuring maternal sensitivity and considerable variation in methods of measurement exists (Shin et al. 2008). Although arguments for standardization of the measurement of breastfeeding have been made (Labbok and Starling 2012), measurement continues to be inconsistent, with different definitions of breastfeeding intent, initiation, and duration, especially with respect to degree of supplementation or exclusivity. In addition, many factors, such as demographic characteristics and prior breastfeeding experience to name a few, influence breastfeeding choice and success (Brockway et al. 2017), and studies vary with respect to inclusion of such confounders.

Breastfeeding, sensitivity, and attachment share several characteristics. Among these are common endocrine aspects (Olza-Fernandez et al. 2014). Moreover, breastfeeding and sensitivity share common affecting factors. Both are positively impacted by a positive maternal emotional state that includes social support and high self-esteem (Britton and Britton 2008; Shin et al. 2008) and negatively impacted by postpartum depression (Dennis and McQueen 2009), anxiety (Britton 2007), and perceived stress (Mezzacappa et al. 2002). Compared to mothers who bottle feed their infants, breastfeeding mothers have been reported to provide a more enriched home

environment for the infant, together with greater variety of daily stimulation and play and less authoritarian parenting approaches (Jacobson et al. 1991). Attachment has been noted to be transmitted across generations (Behrens et al. 2016; Sette et al. 2015), and mothers who were breastfed as infants are more likely to breastfeed their own infants (Di Manno et al. 2015). However, no studies have explored attachment and breastfeeding in the same intergenerational population.

Breastfeeding and Sensitivity

Compared to bottle feeding mothers, breastfeeding mothers have been shown to demonstrate more elevated sensitive behaviors, such as touch, tactile stimulation, and gaze to infant (Lavelli and Poli 1998). They also demonstrate greater attentional engagement with infant distress signals (Pearson et al. 2011) and enhanced activation in brain regions associated with higher maternal sensitivity by MRI scan (Kim et al. 2011). Longitudinal investigations of breastfeeding and maternal sensitivity over the first decade using data from 1,272 families in the NICHD Study of Early Child Care and Youth Development (Papp 2014; Weaver et al. 2018) found that longer breastfeeding during the first 3 years predicted increased maternal sensitivity up to child age 11 years. Several smaller longitudinal studies have demonstrated an association of breastfeeding during infancy with later sensitivity (Britton et al. 2006; Edwards et al. 2015; Jonas et al. 2015; Tharner et al. 2012). One study noted that compared to breastfeeding mothers with low sensitivity, mothers with high sensitivity were more likely to breastfeed either partially or exclusively for longer periods during infancy (Britton et al. 2006).

In a recent review of 43 studies of the association of responsive feeding during infancy and breastfeeding, Ventura (2017) found that cross-sectional studies consistently showed greater maternal feeding responsiveness among breastfeeding mothers than among bottle feeding mothers. He also noted that a limited number of

Weaver et al. 2018	Longitudinal, National Institute of Child Health and Human Development Study of Early Child Care and Youth Development recruited in 1991 after birth in 10 US sites; assessments at: 1,3,6,12,15,24,36,42,46,50,54 months and 5,6,7,9,11 years	1,272 mother-infant pairs; Maternal <i>Education</i> : 30% high school or less <i>Ethnicity</i> : 13% African American <i>Mean annual income</i> : \$37,000 USD	Attachment Q-Sort at 2 years	Maternal and paternal sensitivity in free play and problem-solving task assessed by videotaped sessions eight times between birth and child age 11 years	<i>Duration</i> as continuous variable assessed by maternal recall at each visit until cessation; dichotomous variables for breastfeeding at 6 weeks and at 6 months	Maternal race, ethnicity, years of education, romantic partner in home

longitudinal studies reported that greater responsiveness during early infancy predicted longer breastfeeding duration. Most also showed that breastfeeding mothers demonstrated greater increases in responsiveness across infancy than bottle feeding mothers. Two randomized trials that attempted to promote maternal responsiveness did not observe effects of the intervention on breastfeeding outcomes.

Breastfeeding and Attachment

Although a moderately large number of studies have addressed the relationship between breastfeeding and sensitive maternal behaviors, most have not included measurements of attachment security. The few studies that have explored the relationship of breastfeeding with attachment security are shown in the Table.

Britton et al. (2006) found no differences in breastfeeding practices between securely and insecurely attached infants. However, although Tharner et al. (2012) found an association between breastfeeding duration and attachment security in the Strange Situation, breastfeeding duration was not associated with differences in attachment classifications. It did, however, lower risk of the disorganized attachment classification. In a twin study using data from the Early Childhood Longitudinal Study: Birth Cohort (ECLS-B), Jackson (2016) found that breastfeeding duration predicted security of attachment among female but not male toddlers. In females, each additional month of breastfeeding increased the odds of a secure attachment classification by 15% and decreased the odds of obtaining an ambivalent classification by 15%; in males, breastfeeding duration was actually associated with a higher risk of avoidant attachment classification.

In an analysis of data on children from 9 months to 2 years from the National Center of Education Statistics, Gibbs et al. (2018) found an association of attachment security with predominant antecedent breastfeeding for 6 months or more. In a longitudinal investigation of breastfeeding and maternal sensitivity over the first

decade using data from 1,272 families in the NICHD Study of Early Child Care and Youth Development, Weaver et al. (2018) found that longer breastfeeding predicted secure attachment at 24 months.

Several studies addressed mediation effects of breastfeeding, sensitivity, and attachment. Tharner et al. (2012) found that sensitivity did not mediate the association of breastfeeding duration with attachment security. Weaver et al. (2018) observed that secure attachment at 24 weeks did not act as a mediator of the link from breastfeeding duration to sensitivity later in childhood. However, in a path analysis Britton et al. (2006) demonstrated a significant path between prenatal intent to breastfeed and attachment security mediated by early sensitivity.

Although all of these studies provide data to suggest a relationship between breastfeeding and attachment, none is conclusive and proof of a causal relationship is lacking.

Interventional Studies

A number of interventions have been implemented to foster attachment security and/or maternal sensitivity, but none has reported a concomitant improvement in breastfeeding (Wright and Edginton 2016). Programs to specifically promote breastfeeding have been described, and some have been shown to foster improved infant health at the community level (Brockway et al. 2017). However, none of these studies has reported enhanced attachment security coincident with breastfeeding improvement.

Skin-to-Skin Contact

Skin-to-skin contact between mothers and their infants immediately after birth, also called kangaroo mother care, is an increasingly common practice that has been associated with increased breastfeeding (Conde-Agudelo and Diaz-Rossello 2016). Although such contact could be considered a form of sensitivity, its relationship to the development of later attachment security has not been

adequately addressed (Conde-Agudelo and Diaz-Rossello 2016).

Maternal-Infant Bonding

Breastfeeding is believed to foster the development of a “bond” between the mother and infant in early infancy. In an early study (Klaus et al. 1995), mothers who nursed their infants during the first 3 h after birth and then spent more than 15 h with them over the next 3 days displayed greater emotional attraction to their infants 1 month later compared to mothers with minimal postpartum contact. The term “bonding” refers to the tie from parent to infant, a tie unique and specific to that relationship (Klaus et al. 1995). Although the effect of this bond is generally felt to be enduring (Klaus et al. 1995), the concept of bonding is incompletely defined (Behrens et al. 2016), and an association between early bonding and later attachment security remains to be established (Rode et al. 1981).

Conclusion

Existing data from a limited number of published empirical studies suggests a possible relationship between breastfeeding and maternal-infant attachment. However, such a relationship remains inconclusive, and there is no data to support a causal relationship between breastfeeding and attachment security.

Definition

The biologically normal contents of human milk

Introduction

Human breast milk is a complex and adaptive fluid, comprised of a vast array of bioactive substances. The function of human milk is not only to provide essential nutrition to the breastfeeding infant, but also to enhance growth and development, modulate immunity, and encourage the establishment of a diverse microbiome (Andreas et al. 2015). The exact formulation of human milk is subject to huge variation. This is because the determination of the contents of human milk is through a complex interplay of maternal, infant, and environmental factors. Time-dependent changes further adapt the composition of human milk to align with a growing infant's needs, as milk progresses from colostrum to transitional and finally to mature milk. The culmination of these regulatory mechanisms is a biofluid that is specifically tailored and responsive to the needs of the infant. The primary biologically active components of human milk are lipids, protein,

nonprotein nitrogen (NPN), and carbohydrates (Andreas et al. 2015).

Components of Human Breast Milk

Lipids

Lipids are the primary energy component of human milk, providing approximately 50% of the total energy consumed by the breastfeeding infant (Koletzko et al. 2001). Human milk lipids have also been described to play a role in early growth and development. The entire milk fat content of human milk, present as an emulsion, changes from colostrum to mature milk and is the most variable component of human milk in terms of concentration (Michalski et al. 2005). The mean fat concentration of mature milk is thought to be approximately 3.60 g/dl, though this varies between individuals (Koletzko et al. 2001). Human milk contains a complex mixture of lipid species, predominantly triglycerides which make up over 98% of total fat content (Demmelmair and Koletzko 2018). The remaining lipids are diacylglycerides, monoacylglycerides, free fatty acids, phospholipids, and cholesterol (Koletzko et al. 2001).

A human milk fat globule is 4–5 μm in size, comprising of a triacylglycerol-rich core surrounded by a milk fat globule membrane.

The fat content of milk is present as milk fat globules (Image 1). These globules are formed in the mammary alveolar cells and are comprised of a membrane of polar lipids and a triglyceride-rich core. These globules are larger in the colostrum of women postpartum than in both mature human milk and in infant formula (Zou et al. 2012).

Importantly, the structural differences of milk fat globules between these milk types may change the nutritional value for the infant. A structural component of the fat globule membrane, sphingomyelins, are important for normal neurobehavioral development due to their involvement in myelination of the central nervous system (Lopez and Ménard 2011).

More than 200 fatty acids are present in human milk in varying concentrations. The majority of these fatty acids are present at very low concentrations, and some fatty acids (such as oleic, linoleic, and palmitic acids) dominate (Koletzko et al. 1988; Martin et al. 1993). Both short-chain fatty acids (SCFA) and long-chain fatty acids (LCFA) are present in human milk. The primary function of SCFA is to provide energy to the breastfeeding infant (Koletzko et al. 2001). SCFA are also involved in the maturation of the gastrointestinal tract. LCFA are a component of cell membranes, and their availability in breast milk has been described to play an important role in early human growth and development. LCFA have been seen to accumulate in membrane-rich tissue such as the brain during the perinatal period. It is also thought that the capacity to secrete LCFA varies between humans (Koletzko et al. 2001).

1. Protein

Over 400 different proteins have been characterized in human milk. This vast array of proteins has been shown to provide nutritional, immunological, and developmental benefits to the breastfeeding infant (Molinari et al. 2012). The cumulative majority of breast milk protein is

Breast Milk Composition,

Image 1 Human breast milk fat globule

produced by lactocytes, approximately 80–90%. The remaining protein found in milk is derived from the maternal circulation, passed into the lumen via transcytosis (Peaker 1985). As is the case for most components of breast milk, total protein content declines from early lactation (14–16 g/L) to mature milk (7–10 g/L) (Lönnerdal 2003).

Milk proteins are commonly classified into three groups; mucins, caseins, and whey proteins. Mucins are the structural proteins of the milk fat globule membrane (Lönnerdal 2003). Only a small proportion of human milk is comprised of this group. Caseins are present in higher quantities at approximately 13% of total milk protein (Lönnerdal et al. 1987). There are three casein subtypes, α -, β -, and κ -caseins, which are found together with calcium phosphate in casein micelles suspended in milk. These micelles are of an average diameter of 150–200 nm (Dalgleish and Corredig 2012).

Whey proteins are differentiated from casein proteins by their solubility, as whey proteins are not contained in micelles but are present in solution (Lönnerdal 2003). Whey proteins contain important host defense factors. For example, lactoferrin and lysozymes have synergistic bactericidal properties and have been shown to kill Gram-negative bacteria in vitro. These proteins also modulate immune function. Other whey proteins that are present in high quantities in human

milk include α -lactalbumin, IgA, and serum albumin (Lönnerdal 2016) (Image 2).

Nonprotein Nitrogen

While the nonprotein nitrogen (NPN) content of human milk is a relatively understudied area, it comprises approximately 25% of total nitrogen in milk and represents a diverse range of molecules. These include nucleotides, amino acids, peptides, urea, and creatinine (Zhang et al. 2013).

Free amino acids account for approximately 8–22% of total NPN, primarily glutamine, glutamic acid, and taurine. Glutamic acid and glutamine represent almost 50% of this fraction. These amino acids are thought to be important in early development, yet their exact role has not been defined (Zhang et al. 2013). Nucleotides are known to be essential for a variety of cellular processes such as normal metabolism. Breast milk nucleotides have also been shown to be an advantageous factor in immune function, establishment of the gut microbiome, and maturation of the gastrointestinal tract (Gutiérrez-Castrellón et al. 2007; Hess and Greenberg 2012).

Antibodies

Given the relative immaturity of the adaptive immune system in the first few months of life, infants largely rely on maternal antibodies for disease-specific immunity. These antibodies are transferred to the infant both transplacentally and

Breast Milk Composition, Image 2 Protein composition of breast milk

Breast Milk Composition, Image 3 Transfer of disease-specific passive immunity via breast milk

via breast milk (Chucuri et al. 2010). Neonatal secretions contain very low amounts of endogenous antibody; thus, the breastfeeding infant relies on breast milk antibodies for protection at the mucosal surface against invasive pathogens (Li et al. 2014). These antibodies are predominantly secretory Immunoglobulin A (sIgA), with secretory Immunoglobulin G (sIgG) and serum-derived IgG also present. Breast milk antibodies are hypothesized to be the most important protective immunological component of breast milk. SIgA likely provides this protection via direct inhibition of invasive pathogens at mucosal surfaces. This is likely achieved through neutralization of toxins and virulence factors, immobilization of the pathogens, and prevention of epithelial adhesion (Brandtzaeg 2007) (Image 3).

In response to antigens from the environment, the maternal mucosa-associated immune tissue causes the release of B lymphocytes to mucosal surfaces. This gives increased disease-specific antibody (primarily IgA) in breast milk, which provides increased disease-specific immunity through a variety of methods.

Antigenic stimulation of mucosa-associated lymphoid tissue (MALT) in both the gut and the

airways determines the antibody content of breast milk. The antibodies found in breast milk are determined in response to the infectious agents encountered by the mother throughout pregnancy. Thus, they provide protection against the pathogens the neonate is most likely to encounter in their external environment (Brandtzaeg 2003). Specific sIgA commonly found in breast milk are against pathogens which cause disease in the gut and respiratory tract. These include bacterial species such as *E. coli*, *Shigella*, *Campylobacter*, *Group B Streptococcus*, and *H. influenzae*, as well as viruses such as rotavirus (Le Doare and Kampmann 2014; Van De Perre 2003).

Vaccination of expectant mothers against common infant infections has become routine in many high-income nations and has been shown to be a highly effective prevention strategy. Antenatal vaccination works by increasing both the antibodies passed to the infant via the placenta and the antibody concentrations in breast milk against vaccine antigens. For example, the recent introduction of antenatal vaccination against *Bordetella pertussis* in the United Kingdom resulted in a sustained reduction of over 90% of both infant deaths and hospitalizations due to

pertussis infection (Amirthalingam et al. 2016). Although increased transplacental transfer of serum IgG is likely the main driving force behind the efficacy of antenatal vaccination, studies have shown that increased disease-specific breast milk IgA is also a protective factor for breastfeeding infants against a multitude of infections in the upper respiratory, lower respiratory, and gastrointestinal tracts. Antenatal vaccination, therefore, augments the protection afforded to breastfeeding infants against vaccine preventable infections via the resultant increase in breast milk antibody levels (Li et al. 2014).

Carbohydrates

There is a wide array of carbohydrates present in breast milk. The carbohydrate found at the highest concentration in human milk is lactose. Lactose is a disaccharide of glucose and galactose and is hypothesized to be at such high levels in breast milk to meet the energy demands of the human brain. Another important component of human milk carbohydrate is human milk oligosaccharides (HMO), which serve as nutritional factors for the gut microbiota (Coppa et al. 1993).

HMO are present in high concentrations in human milk. At 4 days postpartum, levels of HMO are on average 20.9 g/L and 12.9 g/L in mature milk. These oligosaccharides are built of five different monosaccharides: L-fucose, D-glucose, D-galactose, N-acetylglucosamine, and N-acetylneuraminic acid and with lactose at the reducing end (German et al. 2008). These monosaccharides are bound in varying orientations and sequences to give a vast array of HMO. Over 200 different HMO, derived from maternal lactocytes, have been identified in human milk. The specific breast milk HMO profile is predominantly determined by the mother's genotype. Four main genotypes have been described for oligosaccharide expression in breast milk. It is believed that while there are differences between these genotypes in terms of the types of oligosaccharides present, the total expression of oligosaccharide between genotypes is relatively similar (Thurl et al. 1997).

HMO influence the cells of the intestinal epithelium, inducing apoptosis and differentiation of

cell lines (Kuntz et al. 2009). HMO have also been shown to act as modulators in allergen-specific immunity by suppressing Th-2-type responses in those prone to atopy (Eiwegger et al. 2010). The immunological action of HMO is also via the support of beneficial bacteria within the gastrointestinal tract. HMO encourage the growth of these bacteria, thereby preventing colonization by disease-causing species. By this mechanism, HMO may prevent neonatal gastrointestinal or respiratory infections (Morrow et al. 2004). Gastrointestinal immunity is further enhanced via the action of HMOs as receptor decoys. HMO are similar in shape to the surface carbohydrates of intestinal epithelium, which are a binding site for many pathogenic bacteria. In mimicking the structure of these carbohydrates, HMO bind bacteria in the mucosal layer and inhibit bacterial adhesion to the intestinal epithelium thus allowing bacteria to pass through the gastrointestinal tract without causing disease (Triantis et al. 2018) (Image 4).

Human milk oligosaccharides are similar in shape to pathogen binding sites on the intestinal epithelium of infants. They bind invasive pathogens in the intestinal lumen, thereby preventing adhesion and invasion of pathogens, allowing pathogens to be excreted without having caused disease.

It is important to note that disease-specific protection and induction of certain cell processes is dependent on the types of HMO ingested. Given the HMO profile of an individual mother's breast milk is genetically determined, it follows that both the composition of the gut microbiota and the disease-specific protection provided to breastfeeding infants may be highly influenced by the mother's genotype.

Factors Influencing Breast Milk Composition

Time-Dependent Changes

Human breast milk begins as colostrum in the first few days postpartum before progressing to transitional milk and then mature milk at approximately 2 weeks postpartum. The transitions occurring between these categories are not distinct, instead

Breast Milk Composition, Image 4 Human milk oligosaccharides as receptor decoys

occurring as a more gradual process through progressive changes in breast milk composition. Colostrum begins with a relatively high whey protein concentration, with low casein, lipid, and lactose concentrations. Throughout the progression to mature milk, the lipid fraction increases. Included in the high whey protein levels of colostrum is a higher proportion of growth factors as well as higher total antibody, likely to supplement the immature infant immune system throughout the immediate postpartum period. Indeed, HMOs are also more concentrated in colostrum, again most likely to augment neonatal immunity (Saint et al. 1984).

Breast milk is also different in its composition depending on the timing of the most recent feed,

as well as within the period of a feed itself. There is high variability of both lipid and lactose levels throughout a feed (Hyttén 1954). Where lipid levels peak at the end of a feed, lactose levels in milk have been shown to decline as a feed progresses. Total milk fat content then declines as the time since the last feed lengthens. Lipid levels have also been shown to exhibit diurnal variation, peaking midmorning with an overnight trough (Coppa et al. 1999).

Maternal Factors

There is some evidence to show that certain maternal characteristics have the power to alter the composition of their breast milk. While maternal

age and ethnicity are unlikely to play a significant role in determination of breast milk composition, maternal diet has been shown to alter human milk (Andreas et al. 2015). The processes behind dietary regulation of milk are complex and differ between nutrients. For example, it is thought that the total lipid fraction of human milk is not influenced by dietary changes. Instead, individual species of fatty acids which are derived from maternal plasma or synthesized by the mammary gland are sensitive to a change in maternal diet (Innis 2014). Fatty acids such as monounsaturated omega-3 fatty acids have been seen to be increased in those mothers who increase their dietary intake (Novak and Innis 2011). It is important to note, however, that there is not a great deal of evidence linking maternal weight gain during pregnancy with higher milk fat content (Andreas et al. 2015).

Conclusion

Human milk provides essential nutrition to the breastfeeding infant during an intense period of growth and development. Further, human milk acts as the safety net for the relatively immature neonatal immune system, through both the transfer of passive immunity and the modulation of immune processes. The biologically active components of milk do not exist in static proportions but change in response to a myriad of factors. The precision of these regulatory mechanisms is a result of millennia of human evolution, culminating in a biofluid that is optimized to meet and respond to the needs of the growing infant.

Definition

Advantages for the mother and child when the newborn is fed with breast milk as opposed to alternative nutritional sources such as formula.

Introduction

Breastfeeding has been highlighted as one of the most important practices for the protection of infants from pathogens during the first years of life (Morrow et al. 2005). This protection is needed to support the newborn's immature immune system after leaving the predominantly sterile womb (Niers et al. 2007). While the immune system is developed before the baby is born, it lacks experience at combating specific pathogens. As a result, maternal (IgG) antibodies are transferred to the fetus in the months leading up to the birth, supporting the immune system while it is vulnerable (Niers et al. 2007). These prenatal antibodies lose effectiveness over the first 3 months; however, breast milk has evolved to extend this assistance for the following months (Niers et al. 2007). Breast milk, though originally considered sterile, is teeming with probiotic bacteria for the digestive system of the newborn, serving to support their immune system and metabolism (Fernández et al. 2013).

Current knowledge concerning the benefits of breastfeeding almost unanimously advocate the exclusive use of breast milk for the first 6 months. There are a wide variety of substantial benefits to both mother and child, supporting the

evolutionary perspective that, as with the majority of mammalian species, humans have evolved breast milk that is tailored to maximize the likelihood of the survival of mother and child (Labbok et al. 2004).

Mortality Rate

Research concerning the risk of death within the first months of life suggest that exclusive breastfeeding has only 12 % of the mortality risk associated with not breastfeeding within low- and middle-income countries (Sankar et al. 2015). High-income countries have also been linked with lower death rates, with evidence suggesting a reduced mortality specifically concerning sudden infant death syndrome and necrotizing enterocolitis (Victora et al. 2016).

Additionally, the timing of the first feed has also been linked with a reduction of infant mortality risk. A systematic review of relevant research suggested that breastfeeding within an hour of the birth substantially decreased the risk of mortality (Khan et al. 2015). Furthermore, following this initial feeding, only partially breastfeeding the child (feeding with breast milk but also from other sources) increased the risk of mortality during the first month for the infant.

Researchers have suggested that interventions designed to optimize global breastfeeding practices could prevent 13 % of the global mortality of children less than 5 years of age (Jones et al. 2003). Supporting this, a review of studies assessing the benefits of breastfeeding to children between the ages of 6 and 23 months suggested that up to a 50 % lower risk of death was observed with continued breastfeeding (Victora et al. 2016).

Infection Risk

The bolstered immunity provided thorough breastfeeding results in a reduction in frequency and duration of infections (Fernandez et al. 2013). Research relating to this typically focuses on the protective effect on instances of diarrhea,

respiratory infections, otitis media (infection of the middle ear), and gastrointestinal infections.

Of these, diarrhea is especially costly and is estimated to be the basis of over 20 % of child deaths under the age of 5 in developing countries (Morrow et al. 2005). The glycans (complex carbohydrates) within breast milk contribute to the passive immunity gained from the mother and are linked directly with protection from diarrheal diseases (Lamberti et al. 2011). Research suggests that breast milk reduces the frequency of diarrhea, but more significantly reduces the duration of each episode (Lamberti et al. 2011). Victora et al. (2016) estimate that half of global diarrhea instances could be avoided through optimal breastfeeding practices.

Additional Benefits

A wide variety of additional benefits have been associated with breastfeeding with varying levels of empirical support. Consumption of breast milk in excess of the first 6 months has been reported as lowering childhood malignancies such as leukemia (Amitay and Keinan-Boker 2015), improved connection created between mother and child (Khan et al. 2015), better oral health (preceding 12 months of age), lower chances of obesity, and a reduction in asthma levels (Victora et al. 2016).

While these benefits for the child are relatively accepted within the scientific community, there are other proposed benefits that are more contested. While some studies have found a protective effect from allergies, the recent review by Victora et al. (2016) found little evidence to support the association. Some researchers have also proposed neurodevelopmental advantages of breastfeeding, such as increased scores on intelligence tests, though these are highly debated.

Benefits for the Mother

Breastfeeding has also been evidenced as having a variety of benefits for the mother in addition to the child. Both breast and ovarian cancer have been associated with a reduced reported frequency of

occurrence relating to the amount of lifetime breastfeeding (Victora et al. 2016). There are also reports that bone mineral density is increased through breastfeeding, though this is contested among the research.

Conclusion

Humans have evolved to produce a highly complex nutritional sustenance for newborn children that also serves to protect them from pathogens while their immune system is immature. Though imitations of this adaption have been created, there is little doubt among the scientific community relating to the superiority of breast milk, especially during the first 6–12 months of life. The proposed benefits include lower rates of infant: mortality, infection, diarrhea, malignancies (cancer), asthma, oral health, and obesity. Additionally, there are also benefits for the mother, primarily relating to lowering the risk of ovarian and breast cancers.

Nursing in modern environments

Definition

The practice of a woman providing breast milk to her own or another woman's child in modern industrialized societies

Introduction

Breastfeeding was long the only viable way of securing infant survival. With that in mind, it is surprising that breastfeeding has evolved to be a somewhat error-prone and complicated process, especially in humans, with reported failure rates of up to 33% due to problems with breastfeeding technique (► “Breast-Feeding”). Historically, wet-nursing (► “Wet-Nursing”) became a common practice (Golden 1996) and can be traced back at least to ancient Roman and Egyptian cultures (► “Breast-Feeding” and ► “Wet-Nursing”). In contemporary Western developed countries like the USA or the UK, however, wet-nursing has become socially unacceptable (see Groskop 2007). And since the invention of artificial formula, it is also less of a necessity.

Despite known health benefits of breastfeeding for mother and infant (see below), we observe a huge variation in breastfeeding behavior in modern societies. In the following, we define breastfeeding behavior to include “*breastfeeding initiation*” (whether a mother breastfeeds her child at all), “*breastfeeding continuation*” (whether the mother continues to breastfeed her child up to a specific duration), and “*breastfeeding exclusivity*” (whether the mother exclusively provides breastmilk to her child or combines breastfeeding with bottle feeding).

Ethnographic and survey research illustrates that cost-benefit calculations play a predominant role in a mother's consideration of which infant feeding method to apply (e.g., Hannon et al. 2000; Radius and Joffe 1988). Whether to breastfeed or not to breastfeed can thus be seen, in part, as a conscious decision-making process. According to the health-belief model, however, it is not the actual costs and benefits that are most predictive for health behavior, including breastfeeding behavior, but it is the beliefs about the costs and

benefits (Emmanuel 2015). In that regard, the health-belief model is a model of bounded rational decision-making, as beliefs about the costs and benefits of breastfeeding may be biased by inaccurate information. In the following, we will therefore not only take a look at some of the actual costs and benefits that can be associated with breastfeeding but also at what sources of information may affect women's beliefs about breastfeeding. Another addition is that the cognitive system that enables people to make rational decisions coexists with a much older system in evolutionary terms that consists of a set of innate, automatic, and domain-specific mechanisms. This view, which is incorporated in dual-process theories (Evans 2003), allows bringing together the social scientific with the evolutionary literature. Whereas the former focuses predominantly on the actual costs and benefits of breastfeeding as well as the factors which affect beliefs about these costs and benefits, the latter addresses potential innate mechanisms that may lead to discriminatory maternal investment within the same families.

Health Benefits and Risks of Breastfeeding

Short of a viable alternative, in ancestral environments breastfeeding was essential for infant survival. It is only with the availability of alternatives (e.g., wet-nursing or artificial formula) that we can ask about the relative benefits and risks of breastfeeding as compared to other feeding methods. The majority of research on the health benefits of breastfeeding in modern environments compares this method to bottle feeding with artificial formula. Previous research shows that due to the immunological benefits of breastmilk, in developing countries, breastfeeding can lower the risk of morbidity and mortality of newborns driven by infectious diseases (Horta et al. 2007; WHO Collaborative Study Team on the Role of Breastfeeding on the Prevention of Infant Mortality 2000). But also in developed countries, often with some form of universal healthcare and advanced medicine, breastfeeding comes with a

number of benefits for the health and development of infants. In fact, a large number of studies exist, summarized in several systematic reviews and meta-analyses, that evidences the positive short- and long-term health impact of breastfeeding for infants (Binns et al. 2016). Breastfeeding protects strongly against many infectious diseases (ebd.), for example, extended breastfeeding in the first two years of an infant's life reduces the risk of acute otitis media (Bowatte et al. 2015). Long-term benefits of breastfeeding include higher performance in intelligence tests and better cognitive development, reduced risk of obesity in childhood and, as adults, a reduction in type-2-diabetes, and a small protective effect against high blood pressure (Binns et al. 2016). For infants born with extremely low birth weight (≤ 1500 g) or born at a very early gestational age (≤ 28 weeks), a systematic review and meta-analysis shows that breastfeeding can also decrease some forms of morbidity common in these risk groups (Miller et al. 2018).

Health benefits of breastfeeding are not limited to the infant but (continued) breastfeeding entails also some benefits for mothers. A recent review and meta-analysis of 163 empirical studies clearly points toward a reduced risk of breast and ovarian cancer, type-2-diabetes, and postpartum depression. And (continued) breastfeeding is also associated with an extended period of lactational amenorrhea. Evidence is not conclusive regarding a potential reduction of the risk of osteoporosis and postpartum weight (Chowdhury et al. 2015). One difficulty in determining the health benefits for women, however, is that certain symptoms like postpartum depression may themselves have a negative causal effect on breastfeeding initiation or continuation (cf. Figueiredo et al. 2013).

Despite the many beneficial effects of breastfeeding for both infant and maternal health, there are specific conditions under which breastfeeding may turn into a disinvestment for infants. This can be the case, for example, if a mother is affected by an infectious disease (e.g., HIV) or exposed to toxins that can be transmitted through breast milk (e.g., Dennis 2002; Bose-O'Reilly et al. 2008). Also, continued exclusive

breastfeeding can turn into an (unintended) disinvestment for infants once breast milk alone doesn't provide sufficient nutrition necessary at later stages of development (Fewtrell et al. 2007).

Other Benefits (and Costs) of Breastfeeding

If women experience discomfort, pain, or stress associated with breastfeeding, these symptoms can be considered costs of breastfeeding that a woman weighs against the known benefits of breastfeeding for herself and for her infant. Discomfort or pain could be experienced, for example, associated with postoperative pain and limited mobility after a caesarian or due to other physical or mental health conditions women may experience postpartum (Beake et al. 2017; Falceto et al. 2004). Also, work-related aspects may influence the extent to which breastfeeding is perceived as stressful or difficult. In the USA, for example, women of low status need to return to their jobs earlier than women of higher status for financial reasons and are thus disproportionately affected by the potential incompatibility of breastfeeding and work demands (Angeletti 2009). It is often higher status jobs that provide (paid) maternal leave that, with the exception of the USA, is provided by the government in many other OECD countries (Thévenon 2011). If a woman works while still breastfeeding, the specific arrangements of the workplace or the work contract may facilitate or hinder continued breastfeeding (Angeletti 2009; Galtry 1997). It is often more difficult to reconcile work and breastfeeding demands for mothers working in low-status occupations as these often provide a lower degree of flexibility (Galtry 1997).

The personal network (kin and non-kin) of a woman can be a supportive factor and thus reduce the costs associated with breastfeeding. Particularly the partner and mother of a woman are potentially influential support persons and sources of information about breastfeeding (Cisco 2017). Therefore, including these support persons in breastfeeding promotion can indirectly affect breastfeeding behavior. A recent review and

meta-analysis of intervention studies targeting the partners, that is, the children's fathers, in their promotion of breastfeeding comes to the conclusion that this type of intervention is positively associated with maternal knowledge about and favorable attitudes toward breastfeeding as well as with breastfeeding exclusivity 6 months after birth. In addition, involving fathers in the promotion of breastfeeding was negatively associated with the risk of lactational problems (Mahesh et al. 2018). Furthermore, contact to peers is positively associated with breastfeeding exclusivity, yet less so in countries where formula feeding is widespread (Sudfeld et al. 2012).

Organizations Influencing Women's Breastfeeding Decisions

International organizations, institutions of the public health sector, the formula food industry, and the media – all with their own sets of interests – target female decision making with regard to breastfeeding. For example, referring to established benefits for infant and maternal health, the WHO and UNICEF as well as government-led initiatives have followed the goal of increasing breastfeeding initiation, duration, and exclusivity (Dennis 2002; Guise et al. 2003, p. 70). Educational programs were set up to educate women about the (health) benefits of breastfeeding. Furthermore, support programs were initiated to provide women with breastfeeding instruction and support. Evaluation studies, summarized in reviews and meta-analyses, show that these do indeed have positive effects on breastfeeding initiation, duration, and exclusivity (summarized in Schnettler 2010). Another countervailing influence is the baby food industry. Not long ago, it was a common practice that it provided free commercial discharge packages along with promotional material on artificial formula via hospitals, a practice with moderate adverse effects on breastfeeding initiation, duration, and exclusivity (summarized in Schnettler 2010, pp. 85–87). Also, the media may have played a role in promoting bottle feeding for a long time. A content analysis of British newspapers and television

programming, for instance, shows that bottle feeding was shown more often than breastfeeding in the respective contents and in a way that made bottle feeding appear to be associated with higher status (Henderson et al. 2000).

Differences in Breastfeeding Between and Within Mothers

We have seen that characteristics of the immediate and wider social context affect women's breastfeeding decisions either directly by changing the cost-benefit ratio (e.g., by means of providing support or giving away free baby food) or indirectly by affecting the beliefs about breastfeeding and the information available about the benefits of breastfeeding vs. bottle-feeding. If the (perceived) costs and benefits of breastfeeding for an individual mother differ over time, the same mother may reach a different decision regarding breastfeeding initiation, duration, and exclusivity for an earlier-born than for a later-born child. For example, a young mother may not yet know about all the health benefits of breastfeeding and decide to bottle-feed her first child, whereas later on, with more information about those health benefits, she could reach a different decision for her second child. Or, as another example, a mother working for different employers over time, with varying degrees of flexibility and supportive policies for breastfeeding mothers, might have more difficulty keeping up a regular breastfeeding schedule in case of one child and less so in case of another child (Schnettler 2010).

Even though the decision to breastfeed is largely described as the outcome of a rational deliberation based on cost and benefit considerations, this decision-making process may be affected or biased by psychological mechanisms that have evolved during our ancestral past. Discriminatory breastfeeding decisions based on child characteristics would thus constitute another source of variation in breastfeeding behavior within mothers but across their different offspring. From inclusive fitness theory one may derive the hypothesis that parents discriminate their

investment toward offspring with physical or psychological characteristics (endowment) that are correlated with higher mating and reproductive success. This could involve, for example, health and physical beauty. Birth weight and gestational age are often considered proxies for endowment differences. And indeed, children born with low birth weight, despite the known benefits for this group of infants (see above), are less likely to be breastfed. However, this might have to do less with parental discrimination than health issues related to the early birth or the low birth weight that render breastfeeding difficult or not possible at all (cf. Hill et al. 1997). Under conditions of scarcity, age may be another child endowment factor affecting parental investment, as older children who have already survived more risks than younger children imply lower sunk fitness costs (cf., Salmon 2005, pp. 508–511).

A considerable amount of research has been conducted on the main effects of child gender on food allocation by parents, especially with regard to developing countries. Some studies provide evidence for preferential breastfeeding of boys in certain regions in India and China, yet a review of more than 300 studies doesn't provide a clear pattern of daughter disadvantage (Marcoux 2002). A related theory along these lines that has received a considerable academic attention is the Trivers-Willard (TW) hypothesis (► [“Trivers-Willard Hypothesis”](#)). It states that parents' reproductive fitness is increased if they alter the sex of their offspring and/or discriminate their investment based on a child's sex in a direction that is dependent on some measure of parental condition. Although it is not quite clear what parental condition measures are most appropriate and may be related to physiological condition in modern societies (► [“Maternal and Offspring Condition”](#)), empirical studies examining the TW hypothesis in modern environments often use some measure of socioeconomic status as indicator of parental condition. As earlier results were mixed with regard to the TW hypothesis (Schnettler 2010), more recent studies on the TW hypothesis in modern environments have either used large data sets from population registers to be able to detect even small differences, yet could not find a

TW-consistent pattern in their data (e.g., Kolk and Schnettler 2013, 2016), or they have used small elite samples arguing that in such groups expected effect sizes might be considerably larger than in the general population and thus detectable even in smaller samples (Schnettler 2010). A recent study on the 400 individuals estimated to be among the wealthiest US Americans (Forbes 400) reported a statistically significant difference in offspring sex ratio in accordance with the TW hypothesis, but it comes to the conclusion that the effect size is much smaller than reported in previous research. The author discussed sample selection as a potential alternative source for the apparent bias in the sex ratio (e.g., Schnettler 2013). Previous studies specifically with regard to differential breastfeeding along the lines predicted by the TW hypothesis led to mixed results (summarized in Schnettler 2010). Yet, another study that specifically compared differences in breastfeeding behavior within families, thus controlling for unobserved heterogeneity between families, found no TW-consistent pattern (Schnettler 2010).

Other Factors Associated with Breastfeeding Behavior

A common finding is that women of lower socioeconomic status, operationalized by education, occupational status, or income, show lower rates of breastfeeding initiation, duration, and exclusivity (Dennis 2002). One reason for that may be education itself: mothers with less information may know less about breastfeeding and be less able to differentiate the truth-value of various informational offerings from external actors (cf. Bergevin et al. 1983). There are other individual-level differences in breastfeeding initiation, duration, and exclusivity. For instance, there is evidence that African Americans have lower breastfeeding rates in the USA. However, a huge part of this difference may be due to socioeconomic differences (Dennis 2002). Another factor is age: young mother below the age of 20 are less likely to breastfeed their child than older mothers (Dennis 2002, p. 15).

Conclusion

To conclude, all correlates of a mother's personal situation and her breastfeeding decision affect either the cost-benefit ratio of breast versus formula feeding or the beliefs that women hold. They can thus be parsimoniously explained with reference to a rational-choice framework in which women are seen as rational decision makers who try to maximize the net benefits of breastfeeding based on their beliefs about the costs and benefits of breastfeeding. Although evolutionary theory predicts that mothers may differentially breastfeed their children, existing evidence on such differential treatment seems inconclusive. Many studies examining forms of differential breastfeeding are based on small samples and/or, with few exceptions (e.g., Schnettler 2010), rely on between-family comparisons that may be confounded by unobserved differences between mothers.

[Artificial selection](#); [Selective breeding](#)

Definition

Breeding systems refer to the various ways of evaluation and selection of desired genetic traits in a breed or species.

Introduction

The purpose of breeding systems is to promote and preserve genetic traits of interest in a breed or species. Specifically, the practice of breeding systems is the process by which humans breed animals or plants to selectively produce offspring with desired phenotypic traits. Breeding systems should not be confused with mating systems (see ► [“Mating Systems”](#)). Mating systems refer to the various ways in which members of a given species arrange themselves to copulate (e.g., monogamy, polygamy). In contrast, animal breeding and plant breeding involve choosing male and female individuals within a species due to their desirable genetic traits and inducing them to sexually reproduce and have offspring that will express such traits. Humans may employ breeding techniques to select traits for various purposes, including selection of aesthetically improved fur in dogs

(e.g., Clutton-Brock 1995), or satisfaction of specific market standards for financial benefits, such as the commercial beef cow herds (Hammack 2003). In the last century, the controlled exploitation of breeding systems to produce certain phenotypical traits has become a common practice in agricultural and laboratorial contexts.

The practice of breeding systems in both plants and animals has records from early prehistory (Wright 1932). Archeological records have shown that plant species, such as rice and wheat, and animal species, such as dogs, have been significantly different from their ancestors (Ahn et al. 1993). For example, there is supportive evidence showing that cashew (*Spondias purpurea*) was selectively bred in Mesoamerica (Miller and Schaal 2006). There are records of active use of breeding techniques from thousands of years ago (Lush 2008) – for example, breeding systems were practiced by the Romans, and techniques of selective breeding were found in the Persian culture (Wilczynski 1959).

In the eighteenth century, the agriculturalist Robert Bakewell contributed significantly to the development of breeding systems, playing an important role in the British Agricultural Revolution. Bakewell systematically and successfully applied selective breeding on livestock. Bakewell’s techniques led to significant advances in the genetic quality of sheep, cattle, and horses and contributed to the development of the breeding systems field (Zeuner 1963). Accordingly, Charles Darwin provided a compelling explanation on how selective breeding and domestication of various animals, such as cats and dogs, produced variation over time (see Darwin 1859).

Several innovative techniques have been developed to manipulate the genetic value of a given domestic livestock. For example, *pure-breeding*, or sometimes referred as *true breeding*, involves producing offspring by inducing genetically similar individuals to sexually reproduce (Lush 1946). The *inbreeding* technique refers to the manipulation of the occurrence of desired genetic traits by breeding genetically related individuals (Dickerson 1973). *Outbreeding* refers to a cross between individuals of a single breed

that are not closely related (Dekkers 2004). *Cross breeding* is a breeding technique in which two individuals of different breed or species produce offspring, thus combining desirable qualities of genetically unrelated individuals (e.g., Labradoodle, a crossbred dog derived from the Labrador Retriever and Poodle; Trivedi 2004). For a detailed review of the various breeding systems and techniques in plants and animals, see Richards (1986) and Clutton-Brock (1988), respectively.

Breeding Systems

Pure-Breeding

A purebred (also true bred, or pedigree) individual refers to the progeny of any two individuals in a breed that presents consistent, replicable, and predictable characteristics (Lush 1946). For example, an offspring from two purebred dogs of a single breed (say, Labrador Retriever) will exhibit the phenotypical traits of its parents (i.e., pure or pedigree Labrador Retrievers) and not the traits of the offspring's ancestral breeds (Parker et al. 2004). The purpose of purebred production is to select desired, specific phenotypical traits to serve a market niche, such as livestock industry.

Historically, humans have been using pure-breeding techniques in several animals. For example, purebred dogs are usually a modern breed of dog (Parker et al. 2004). The domestication of the horse caused the appearance of some domesticated stallions (Wade et al. 2009). Several purebred cats have been developed by humans due to their commercial benefits. In fact, cat registries identify between 40 and 70 breeds of cats (e.g., The International Cat Association 2017; Fédération Internationale Féline 2017), with new breeds being documented every year, each having unique lineage and features. Most farm animals are purebred, including pigs, goats, and sheep (for a review, see Clutton-Brock 1988).

Because the long-term use of pure-breeding techniques produces a limited gene pool, purebred animals are susceptible to an extensive variety of congenital health complications (e.g., Ackerman 2011). This is particularly

common in contexts where an emphasis on aesthetics overcomes body functionality and healthy immunological system (e.g., competitive dog breeding). Nonetheless, the costs associated with the congenital health problems may be aggravated when breeders use inbreeding techniques (e.g., Afzal 1994).

Inbreeding

The inbreeding technique results in offspring produced by genetically related individuals (Dickerson 1973). Inbreeding is often used to expose deleterious alleles. Specifically, inbreeding promotes homozygosity, thus increasing the odds of offspring to express deleterious or recessive traits (Nabulsi et al. 2003). This may lead to a reduced physiological fitness of the inbred stock (i.e., inbreeding depression; Jiménez et al. 1994). Therefore, livestock breeders may use inbreeding techniques, for example, to develop phenotypically enhanced breeds by identifying undesirable characteristics in offspring that will further be eliminated in the next stock generations. Inbreeding in plants often occurs naturally in the form of self-pollination (Richards 1986).

A breeding system was then developed to avoid the expression of deleterious alleles caused by inbreeding procedures – such a technique is referred to as outbreeding (or outcrossing; e.g., Bernstein et al. 1985). Specifically, inbreeding occurs when *genetically related* individuals produce an offspring, and outbreeding occurs when an offspring is produced by *genetically unrelated* individuals within a single breed. Inbreeding and outbreeding are often understood as opposite techniques – despite the debate about the optimal genetic relatedness for inbreeding and outbreeding systems (e.g., for a software for relatedness and inbreeding coefficients, see Wang 2011). Inbreeding techniques are often comprised by a genetic relatedness that varies from full brother and sister to cousins (e.g., Clutton-Brock 1988).

Outbreeding

Outbreeding (or outcrossing) is a breeding procedure that involves the insertion of unrelated genetic traits into a breeding line. Outbreeding

usually increases the genetic pool within a population, thus reducing the likelihood of an individual to express deleterious alleles that may cause congenital health problems (e.g., Dickerson 1973). In outbreeding, breeders may find individuals in a stock that are distantly related to a common ancestor, since all individuals within the species are susceptible to express a genetic trait if the genetic trait is carried throughout the generations (i.e., the founder effect; Ladizinsky 1985). Therefore, well-established breeds often present a large gene pool, and such a variety of genetic expression increases heterozygosity (i.e., variability and diversity of phenotypes).

Outbreeding is the most common used breeding system by commercial breeders (Dekkers 2004), since outbreeding breeders often need to increase heterozygosity to eliminate undesired genetic traits, to therefore satisfy commercial standards. As a breeder detect the desired genetic traits, he or she may strategically induce mating to eliminate associated undesired genes, thus preserving the desired ones. By doing so, breeders produce a breed that satisfies the commercial standards and that may be further used for inbreeding. Because the desired traits do not always correspond to the traits expressed by dominant genes, the outcrossing breeder may end up with breeds having several deleterious alleles – for example, many dog breeds express deleterious traits that cause congenital health problems (e.g., Parker et al. 2004). This is possible because outbreeding allows for the recessive traits to propagate throughout a population (Dekkers 2004).

Crossbreeding

The crossbreeding technique describes crosses between different breeds within a species. That is, a crossbred usually refers to an individual with purebred parents of two different breeds. The practice of crossbreeding is a well-accepted practice among commercial breeders (e.g., most lambs in the American market are crossbreds; Beermann et al. 1995). Crossbreeding allows breeders to produce a breed with a variety of desired genetic traits of two or more breeds (i.e., hybrid vigor; Crow 1948). Breeders should use crossbreeding techniques in a responsible way – some

crossbreeding in the animal industry may lack systematic procedures or may not employ techniques that optimize the benefits of crossbreeding (e.g., “mutt dogs”). For example, although crossbreeding is generally used to provide better health conditions to breeds (Beermann et al. 1995), negligent crossbreeding may promote undesired assortment of a purebred genetic pool, which may eventually lead to the extinction of a breed within a species.

A good crossbreeding technique involves the strategic selection of the genetic traits of different breed to produce a new breed (i.e., crossbred) that satisfies commercial standards (e.g., quality of meat; Touraille et al. 1989). Good use of a crossbreeding system allows breeders to produce a breed with complementary traits – that is, production can be optimized when breeding systems, such as crossbreeding, produce breeds that express the “optimal ratio” between desired and undesired genetic traits (Wright 1932). Crossbreeding may also be used to proliferate a highly desired, rare mutation without incurring the costs of an inbreeding system (e.g., propagation of deleterious alleles; Clutton-Brock 1988). In contrast, crossbreeding systems are difficult to perform with a few individuals from different breeds within a species – the genetic pool provided by the individuals from each breed may not offer enough genetic variance for the breeder to optimally propagate the desired genetic traits (Wright 1932).

Humans have been performing crossbreeding in several species. Some breeds of domestic cat that were recently recognized are crossbreds between existing, well-established breeds (e.g., Lipinski et al. 2008). In cattle, systems of crossbreeding are often used to produce breed with complementary traits. For example, crossbreeding may occur when the breeder induces mating between a purebred female and a purebred bull with desired traits, but that are adapted to different environments, resulting in individuals with desired traits of both parents (Clutton-Brock 1988). Moreover, the various breeds of sheep allow crossbreeding to be used to enhance genetic traits in lambs that may be further used for commercial purposes (e.g., Leymaster 2002).

Conclusion

Breeding systems serve to promote and preserve desired genetic traits in a breed or species. Over the past centuries, humans have developed several breeding systems (e.g., pure-breeding, inbreeding, crossbreeding). Each breeding system has unique benefits, and the use of different techniques may lead to different outcomes. For example, crossbred (vs. purebred) pigs offer substantial advantages for commercial breeders because the expression of certain complementary traits in pigs is key to satisfy the swine industry standards (Stein et al. 1990). Accordingly, most commercial swine producers use crossbred pigs rather than purebreds, especially in the carcass and meat industry (Van Wijk et al. 2005).

Breeding systems are mostly used for commercial purposes. In such a competitive market, where breeders are tempted to use different techniques to rapidly achieve commercial standards, breeding systems should be used in a responsible manner. The genetic consequences of irresponsible use of a breeding system may include a reduction in the frequencies of relevant alleles or genes, which may cause, for example, poor genetic variance or propagation of undesired, deleterious traits.

[Author](#); [Researcher](#)

Definition

Brett Laursen is a professor of developmental psychology specializing in the study of adolescent peer and parent relationships at Florida Atlantic University.

Introduction

Brett Laursen's research is predominately focused on the transmission of influence across the childhood and adolescent years. His previous scholarship includes, but isn't limited to, investigations of longitudinal influence between children and their parents, peers, siblings, friends, and romantic partners. While most of his research does not fall under the purview of evolutionary psychology, Laursen did collaborate with Lauri Jensen-Campbell to propose an evolutionarily informed developmental model of social exchange within adolescent romantic relationships. This model incorporates social exchange theory with evolutionary psychology's precepts regarding mate selection in order to propose how adolescents' romantic behaviors might be driven by different distal and proximal influences depending on their physical, social, and cognitive maturation. The foundations and a description of their model are described below.

Social Exchange Theory

According to social exchange theory, individuals keep track of the rewards and costs of each social relationship and seek to raise the former while minimizing the latter (Thibaut and Kelley 1959). Those with a higher reward/cost ratio were considered more attractive. Revisions to the theory propose that more complex patterns of exchanges are apparent in closer relationships (Kelley and Thibaut 1978). For example, in adult romantic relationships, interactions tend to fall into two patterns: (a) one where each member seeks equality of outcomes across members and (b) one where each is focused on improving both members' outcomes. A further distinction can be made between relationships where each member is focused on their own rewards (e.g., exchange relationships) from those where each member believes their partners' benefits are their own rewards (e.g., communal relationships). In general, when a romantic relationship maintains the same reward/cost ratio between both members and when each member focuses on their partner's

benefits, interdependence increases. As this occurs, romantic relationships are expected to transition from exchange to communal and from an open (voluntary) to a closed (committed or married) status.

Evolutionary Psychology

Evolutionary psychology (Buss 1995; Kenrick and Trost 1989) also provides explanations for mechanisms underlying social exchange in romantic relationships. Evolutionary psychology posits that many aspects of social relationships are adaptations which promoted the survival of human ancestors. Heterosexual romantic relationships were particularly important in this regard. Humans who utilized romantic relationships to increase personal gain and, as a result, survivability were also those who were most likely to bare and raise offspring. Consequently, in prehistory, females tended to seek mates who had greater resources to help offspring, whereas males sought mates who had physical signs of an ability to carry offspring to term (Trivers 1972; Feingold 1992). While these tendencies are apparent today, the mechanisms by which they are manifested are likely colored by the modern world.

A Developmental Model of Social Exchange in Adolescent Romantic Relationships

Building upon both social exchange theory and evolutionary psychology, Laursen and Jensen-Campbell (1999) have proposed a developmental model of social exchange in adolescent romantic relationships. This theory posits that, in the adolescent romantic domain, distal influences such as environmental constraints and evolutionary-based preferences predominate in early adolescence but typically give way to more proximal influences in late adolescence. Importantly, due to limitations in physical characteristics and cognitive abilities, young adolescents are generally limited to exchange relationships which are

focused on self-centered gains. During this time, environmental, cultural, and physical constraints hold heavy influence. For example, in many cultures today, young adolescents' dating-related freedoms are often constrained to prevent early pregnancies. Physically, many young adolescents also have not developed the secondary sexual characteristics needed to be competitive in the eyes of potential partners. Furthermore, young adolescents have not cognitively developed enough to understand that traits such as kindness and compatibility are important considerations in addition to evolutionarily informed signs of physical attractiveness. With age however, many of these limitations subside, and social exchanges grow more complex due to maturational development and changes in social norms. Older adolescents are then in a position to draw upon past experiences and are better able to recognize that beneficial relationships are those that foster individuality, are not driven solely by physical attractiveness but extend to psychological desirability, and are those that are communally focused on fulfilling the needs of both members.

Conclusion

In their developmental model of social exchange in adolescent romantic relationships, Laursen and Jensen-Campbell (1999) build upon social exchange theory to outline a guiding framework for future research on adolescent romantic relationships, an area which is often overlooked. Additional research within this framework may reveal support for the proposed proximal and distal influences of adolescent romantic behaviors, as well as identify important antecedents to the development of healthy adolescent relationships.

Brian Boyd

Ania Grant and Severi Luoto
University of Auckland, Auckland, New Zealand

Definition

Brian Boyd is a leading scholar of evolutionary and biocultural approaches to art, especially literature. He conceives of art as a form of cognitive play with pattern that exercises and refines our creative, cognitive, emotional, and social skills.

Introduction

Brian Boyd is a University Distinguished Professor of English at the University of Auckland. Within literary criticism, he is best known for his work on the Russian-American novelist and

lepidopterist, Vladimir Nabokov. Since the late 1990s, Boyd has also been one of the leading advocates and practitioners of evolutionary, biocultural, and cognitive approaches to the study of art, especially literature and fiction. He argues that art is a human adaptation, a form of *cognitive play with pattern* (Boyd 2009) that has coevolved with human cognition, emotion, and sociality. Boyd stresses the social and cooperative origins and effects of art. All forms of art, especially fiction, can enhance social cohesion and control (Boyd 2009, 2018).

He proposes a *multilevel model* for analyzing art and literature, comprising general evolutionary principles, the distinctly human aspect, local socio-historical variation, individual differences of authors and audiences, and details of particular works. Artists and audiences should be seen as *problem-solvers*, balancing *cost–benefit trade-offs* of the composition and reception processes, with a special focus on the problem of engaging *attention*.

Boyd's most notable works include *On the Origin of Stories: Evolution, Cognition, and Fiction* (2009), which details his account of the evolution and function of art and storytelling; and *Why Lyrics Last: Evolution, Cognition, and Shakespeare's Sonnets* (2012), an evolutionary analysis of nonnarrative verse. He also co-edited *Evolution, Literature, and Film: A Reader* (Boyd, Carroll & Gottschall 2010); and contributed to *Literary Animal: Evolution and the Nature of Narrative* (Boyd 2005), and *Darwin's Bridge: Uniting the Humanities and Social Sciences* (Boyd 2016b). He co-curated, with Steven Pinker, Geoffrey Miller, and Mark Changizi, an exhibition contrasting four different explanations of the origins of human art at the Museum of Old and New Art in Hobart (Boyd 2016a). His recent article, "The Evolution of Stories: From Mimesis to Language, from Fact to Fiction" (Boyd 2018), provides an updated account of the human capacity for and preoccupation with fiction, from mimetic to verbal communication, and from factual to invented stories. Boyd is currently working on *On the Ends of Stories*, and on a biography of Karl Popper, a founder of evolutionary epistemology.

Art as Play with Pattern

Boyd (2009) argues that art evolved from the especially strong human predilection for pattern-recognition (a way to understand the world in real time, common to most organisms) and the predilection for play as a way to hone valuable skills in nonurgent situations (common to all mammals, many vertebrates, and even some invertebrates). The amount of play in a species increases with the level of behavioral flexibility and the degree of sociality. Humans, both highly flexible and social, play even in adulthood. Like other animals, we practice our physical abilities through play. But since humans thrive mainly through the mastery of cognitive and social skills, we practice, refine, and extend them in art. As animal play-fighting, human art is, in Boyd's view, about creative exuberance and self-rewarding fun, but also about acquiring greater sense of control – both of ourselves and of our circumstances.

The Evolution of Fiction

According to Boyd (2009, 2018), in the art of fiction we play with patterns of narrative (agency, causality, context, perspective), language, and social interaction – all elements integral to human thought, communication, and sociality.

Boyd's evolutionary analysis of fiction focuses both on ontogeny and phylogeny (Boyd 2009, 2018). Ontogenetically, fiction develops out of children's pretend play, although such play is also scaffolded by the stories children are told. Phylogenetically, fictional storytelling most likely developed around 400,000 years ago when the invention of campfires allowed additional time for social interaction and information-sharing. Other precursors of fiction include dreams, confabulations, and lies.

Boyd's evolutionary account of fiction holds that the production and comprehension of fiction requires a range of cognitive capacities connected with tracking and recombining of information: event comprehension, memory, imagination, and communication (Boyd 2009, 2018). These have developed in a range of species. However,

increasing human sociality and co-dependence created the selective pressure for more information-sharing, more efficient means of communication, and a better understanding of our conspecifics. The developments of narrative, our main mode of understanding, and language, our main tool of communication, allowed our ancestors to extend their knowledge beyond what they could learn first-hand (Boyd 2018, and references therein). The more we knew about each other, the more such knowledge became crucial to our success, to effective competition and cooperation among individuals and groups. Boyd (2009, 2018) notes that fiction extends our social knowledge even further – to the hypothetical, the imagined, the exaggerated – and presents it in a condensed, evocative form so as to capture our attention and stir our emotions, which in turn amplifies and prolongs its impact.

Social Underpinnings of Art and Storytelling

Boyd (2005, 2009, 2016a) stresses the social and cooperative nature of art (in contrast to Geoffrey Miller's [2000] hypothesis that art developed as a result of the processes of sexual selection). Music, dance, storytelling, and visual arts (body painting, landscape marking, decorating of everyday objects) have been used for millennia to transfer valuable knowledge and skills, honor group traditions, pledge group allegiance, and display group's power and wealth to outsiders. Boyd points out that art depends on individual flair and skill but always in relation to social rules and traditions. Artistic endeavors can bring fame and fortune to gifted individuals but most of art, especially early in human evolution, required social approval and support. Unless the artist's activities were sanctioned by and recognized as valuable for the group, the artist would not gain any prestige or privileges. Also, in many forms of art, artists use their special talents to beautify or acknowledge the status of *others*, not themselves.

Boyd (2009, 2018) maintains that storytelling in particular is connected with our social intelligence, our capacity to understand other people's

thoughts, feelings, and intentions, and our need to monitor their behavior. Stories, both factual and fictional, help us navigate the social realm and serve as a means of social attunement.

Artistic and Biological Adaptation

Boyd (2009) argues that art is a human adaptation, not simply a by-product of human cognitive abilities (as claimed by Steven Pinker, 1997). However, Boyd points out that an evolutionary approach to art and/or literature does not depend on the idea that they are adaptations: it “simply requires that we take seriously that evolution has powerfully shaped not just our bodies but also our minds and behavior” (Boyd 2009, p. 210). More recently, Boyd has argued that “the very opposition of adaptation and byproduct reflects an overly gene- and individual-centered view of evolution” (Boyd 2018, p. 12).

In Boyd’s view, art depends largely on social learning, and the persistence of many artistic conventions may be explained via the coevolution of signals and preferences (Boyd 2016a, and references therein). Some forms of art, such as verse, may be universal, but not necessarily adaptive (Boyd 2011, 2012).

Evolutionary Theory and the Study of Art and Literature

In his approach to art and literature, Boyd (2009, 2017) highlights three aspects of evolutionary theory as particularly relevant: the idea of *continuity and variation*, the *problem-solution model*, and *cost-benefit trade-offs*. Continuity and change are at the heart of evolution and art: long-standing history is the basis for new developments and innovations, and widespread trends include local and individual variations. Evolution is about solutions to recurrent problems of survival and reproduction. The solutions that offer more benefits and/or fewer costs in a given environment are favored by natural selection and persist into future generations. Boyd suggests that art works in a similar way: both artists and

audiences are problem-solvers. They face a range of composition and comprehension problems, but the crucial problem in art is that of *attention* (Boyd 2009, 2017, 2018). Artists seek to engage the audience’s attention while reducing their own invention costs and maximizing benefits, such as prestige or financial rewards. Audience members, consciously or not, weigh up the costs of diverting their attention, time, and energy from other concerns, or from other works of art, against potential payoffs, such as pleasure, information, and intellectual and/or emotional stimulation.

The Importance of Attention

Boyd (2009, 2017, 2018) notes several reasons for the importance of attention. Firstly, attention is a limited resource and is therefore subject to intense competition, both within individual brains where numerous sensory inputs and neural processes compete for metabolically costly neural space, and within social groups where various individuals vie for positive attention as a route to status and influence. Secondly, one of the preconditions of art is the unique human disposition to *joint attention* – noticing something worth others’ attention, drawing their notice to it, and checking that they are attending to the features that caught our attention. And finally, art has to earn the audience’s attention before it can impart any meaning or fulfill any other function.

Multilevel Analysis

Evolutionary sciences seek multilevel explanations, from local ecologies to genes to large-scale societies. Similarly, Boyd (2009, 2016b) argues that the evolutionary analysis of art and literature can and should include multiple interconnected levels: (1) the **global**: evolutionary principles common to human and other species; (2) the **human**: evolutionary principles shared by different cultures and individuals; (3) the **local**: differences in culture, time, and place; (4) the

individual: characteristics of individual authors and audience members; (5) the **particular:** a specific text or work of art; and (6) the **detail:** various elements of each work as separate problems and solutions for the author and/or the audience member. How relevant each of these levels is to any given analysis will depend on the questions raised by the researcher.

Boyd demonstrates how such a model can generate new and exciting insights about the artistic and psychological dimensions of texts as diverse as Homer's epics (Boyd 2009), William Shakespeare's sonnets (Boyd 2011, 2012, 2016b), Art Spiegelman's comics (Boyd 2010, 2016b), and Dr. Seuss's children's books (Boyd 2009).

Conclusion

Brian Boyd has made a significant contribution to understanding the human capacity for and fascination with art, especially literature and fiction. He argues that art arises from and further develops adaptive human predilections for pattern-recognition, play, shared attention, and cooperation. Art boosts human creativity and gives us a sense of control over the uncertainties of our world. It enhances group cohesion while also raising the status of talented individuals. Boyd (2009, 2018) emphasizes that fiction, in particular, emerged from our adaptive predisposition for sociality, information-sharing, and play, and has had a profound impact on individual and social development, emotion, cognition, behavior, and very likely on our genes.

Definition

Brian Hare (Ph.D.) is an associate professor of evolutionary anthropology at Duke University in North Carolina and the founder of the Duke Canine Cognition Center. He received his Ph.D. from Harvard in 2004. He is widely published in many high-profile journals, with articles on dog and primate comparative cognition and psychology. His papers are some of the most cited on dog behavior and intelligence.

Introduction

Dr. Brian Hare is well known both inside and outside the academic community. He has received media coverage both nationally and internationally through “Daily Mail, The Telegraph, The Economist, The New York Times, The New Yorker, National Geographic, Time, The Washington Post, the Los Angeles Times, Nature, Wired, Science magazine, CNN, and ABC (Australia)” (Hare n.d.). In 2004, the Alexander von Humboldt Foundation and the German Federal Ministry of Education and Research named him a recipient of the Sofja Kovalevskaja Award, which is Germany’s most prestigious award for scientists under age 40. In 2007, Smithsonian magazine named him one of the top 37 scientists in the United States under age 36. In 2009, Dr. Hare gave keynote addresses at the annual conferences for the Assistance Dog Training Society and the Association of Pet Dog Trainers, which are among the largest dog training societies in the United States (Hare n.d.).

Professional Work

Dr. Hare is the co-founder of *Dognition* (see www.dognition.com), a service that provides dog intelligence assessments via online video tutorials. Specifically, owners can pay for the Dognition Assessment, which is composed of interactive games and putative expert analyses that are designed to give the client a unique perspective on how their dog sees the world (Dognition 2016).

Data collected through this service is intended to be analyzed and published in scientific journals, benefitting both dog owners (who learn more about their dogs) and researchers (who gain information about dog intelligence and behavior across many dogs from around the world). Dognition’s research has thus far (at least, as of 2017) resulted in the publication of one journal article (Stewart et al. 2015). This study critically examined the reliability of the data collected by dog owners via Dognition, with positive results, and also found that dogs vary independently on multiple cognitive domains based on their performances in different cognitive tasks.

Dr. Hare is also the coauthor of the book “The Genius of Dogs,” written with Vanessa Woods. This book summarizes Dr. Hare’s research on the domestication of dogs and how it influences our understanding of our family pets (Hare and Woods 2013). Furthermore, Dr. Hare has pioneered research on how domestication has affected dog cognition. His research suggests that dogs are born prepared to read human social cues, whereas wolves are not (Hare et al. 2002), and that dogs are excellent at reading human communicative cues and understanding human visual perspectives, which he argues are heritable skills that evolved during domestication via selection based on fear versus aggression toward humans (Hare and Tomasello 2005).

Theory of Mind in Chimpanzees

Although perhaps better known for his work with canines, Dr. Hare is also a major researcher in the field of nonhuman theory of mind, particularly within chimpanzees. Theory of mind is the ability to understand that other animals’ behaviors are caused by mental states. For example, the behavior of gazing at an object can be equated with the mental states of seeing the object and knowing the object is there in humans or other animals with theory of mind. Hare’s two most cited papers on this topic both detail experiments where chimpanzees are allowed to observe each other’s behavior during food (Hare et al. 2000, 2001). In both studies, the authors concluded that chimpanzees were taking into account the visual perspectives and knowledge of other chimpanzees, rather than

just responding to behavioral cues. These two studies, and the conclusions drawn by the authors, have been hotly debated (e.g., Povinelli and Vonk 2003, 2004). See the entry on Canines for more information about dog theory of mind.

Conclusion

Dr. Hare is a leading research in the field of comparative psychology, particularly with regard to dog behavior, cognition, and the process of domestication.

Definition

Marriage transactions from brides and their families to grooms and their families.

Introduction

A salient feature of marriage practices in many traditional societies is the transfer of money, goods, and services at the time of marriage. When these transfers are made from brides and their families to grooms and their families they are broadly classified as dowries. A transfer from the groom and his family to the bride and her family on the other hand is generally termed as a bride price. The custom of marriage transactions is known to have a patterned distribution worldwide (Bergstrom 1993). Out of the 1,267 societies listed in Murdock's Ethnographic Atlas, while two thirds practice bride price, only 6 % follow the custom of dowry (Murdock 1967).

Moreover, whether a given society practices dowry or bride price has also been theoretically linked to a number of socioeconomic factors such as form of inheritance system and residence of the bride after marriage, kinship organizations, dominant mode of production and the consequent economic contribution of women relative to men, social stratification, and availability of brides and grooms in the marriage market. The purpose of this key idea is to examine the body of literature on bridal cost, henceforth dowry, particularly in India, to describe the practice, both past and

present, and to explore the possible reasons for its continued prevalence despite modernization and amendments to laws.

Pre-Mortem Inheritance

A primary feature of the inheritance laws in India is the distinction between joint ancestral property, which includes land and individually acquired property usually parental wealth. Under the Hindu Succession Act before 1956, while a male was entitled to a share in ancestral property by birth and a share in parental property by survivorship, a female was excluded from succession even to her father's property (Carroll 1991). Thus, the practice of dowry can be traced back to the Hindu Succession Laws as they stood before the reforms made in 1956. Given the exclusion of daughter's rights to inherit and virilocality (system in which a daughter leaves her natal home upon marriage) the practice of dowry compensated for the legal restrictions by allowing presentation of wealth to a daughter at an appropriate time, usually her marriage in the form of movable property. Dowry is subsequently viewed as a pre-mortem inheritance of a daughter, *Stridhanam*, which prevents break-up of family property and at the same time increases her bargaining position and resources of her conjugal household (Krishnamurthy 1981; Miller 1981; Sharma 1984).

However, the historical notion of dowry as a form of pre-mortem inheritance that goes to a daughter upon marriage does not explain the variation in the practice of dowry giving. Not all Indian brides are married with dowry nor are dowry givers a purely random sample of the Indian population. Moreover, dowry and inheritance resemble one another neither in timing and value nor the manner in which they are allocated. That the dowry comes at a different time from the male inheritance, is linked to marriage, that it is worth less, and is allocated differently simply indicates that the Indian society has two ways of devolving property, one for sons and one for daughters. While the inheritance for men is guaranteed, without marriage there is no dowry

and hence no inheritance for women (Agarwal 1995). Furthermore, it is not clear, with what justification do poor families, which do not have parental property to share, spend on marriage of their daughter beyond their capacity?

To eliminate the inherent gender inequality in the Succession Laws, reforms were made in 1956 to provide *daughters* and sons an equal share in their father's property. However, a male child's right and a female child's denial to ancestral property by birth remained intact. A number of states in the southwest part of the country further amended the Hindu Succession Act to grant daughter's equal coparcenary rights by birth as enjoyed by their brothers. Specifically, the states of Andhra Pradesh, Tamil Nadu, Maharashtra, and Karnataka passed the amendments in 1986, 1989, and 1994, respectively, to make a daughter's status equal to that of sons (Agarwal 1995). These reforms were adopted nationwide in 2005 thereby making the need for any means of "indirect inheritance" for women redundant. However, while the size of bequest dowries has decreased, the reforms have not prevented the prevalence and spread of the dowry custom across India (Roy 2015).

Kinship Organizations and Mode of Production

Although the practice of dowry is largely driven by limitations on women's access to joint family property in spite of the reforms in the Succession laws, the regional dichotomy observed in the nature of marriage payments especially between North and South India is attributed to the differences in their kinship organizations. While the magnitude and frequency of dowry payments in the North is explained via its preference for marriages outside kin groups of the same or higher social standing and patrilineal inheritance system that denies women rights to family property, prevalence of equal gift giving or bride price in the Southern part of the country is credited to its recognition of women's rights to land, marriages between consanguine, and partners of equal status (Dalmia and Lawrence 2009; Trautmann 1993; Dyson and Moore 1983). It is important to note,

however, that a vast majority of studies illustrating the heterogeneity in marriage transactions between North and South India are based on ethnographies of single villages or districts that are now over 35 years old. In addition, surveys of villages and districts for the purposes of ethnographic studies are likely to describe a community's norms instead of the actual functioning of the marriage markets in the region suggesting further examination of the reasons for the variations in marriage transactions.

To this effect, Goody (1973) suggests that women's role in production, particularly their agricultural labor, is a crucial determinant of whether a bride price or a dowry will be paid at the time of marriage. Accordingly, he attributes bride price in the south to the greater value and participation of female labor in its rice-based agrarian systems and dowry in the north to its reliance on wheat production and hence plough-based cultivation where women do significantly less agricultural work compared to men. Further complicating the landscape, Gulati (1975) and Schlegel and Eloul (1987) find that even regions characterized by low rates of female labor force participation, such as Kerala, Orissa, and Assam, exhibit bride price as the predominant form of marriage payment. Furthermore, when looking at the areas of low female labor force participation stretching from North to East India, what is surprising is that the region encompasses both rice and wheat producing states, suggesting that there is more to the reasoning behind the nature and size of marriage payments observed in India (Miller 1981).

Spread and Escalation of Dowry Payments

In the 1950s a number of anthropologists noticed that communities that had traditionally paid bride prices had begun to pay dowries, while communities that were traditionally dowry paying were subject to dowries of a much greater magnitude. Consequently, a practice that was once confined to some communities among the propertied in North India soon became customary and uniform across all caste and class groups in India. Social anthropologists

often explain the universal adoption of the dowry practice as an outcome of *Sanskritization* – embracement of upper-caste patterns of behavior by members of lower caste as a means of acquiring higher social caste (Srinivas 1984). In other words, the observed shift in regime from bride price to dowry in all castes is simply a case of upwardly mobile behavior. However, this explanation is weak on two counts. First, it is unlikely that the benefit gained by lower castes in behaving like upper-caste *Brahmins* is greater than the immense destitution they often face by paying dowries. According to Anderson (2007) and Bloch and Rao (2002), while average dowry demands ranged between six to eight times the average annual income of the bride's household in the period 1960–1995, the amount of dowry payments increased 15 % between 1921 and 1984. Second, real dowry payments have increased even in castes in which historically dowries have been paid (Rao 1993).

Moreover, conditions in the marriage market also depend upon the availability of marriageable men and women. Where marriage transactions involve wealth transfer by only one gender, they signal a gender bias in the intensity of competition for marriage partners: competition is stronger among (or on behalf of) members of the gender that pays. The idea that a deficit in the population of either gender could influence marriage transactions has been around for some time (Dickemann 1979). As far back as the beginning of this century, Sir Herbert Risley (1915) used the gender imbalance argument to explain why dowry was being practiced at the top of India's hypergamous castes, while bride price prevailed at the bottom of the caste ladder. That is, the upward flow of women produced by hypergamy – practice of a woman marrying a man of superior caste or class – resulted in a surplus of women at the top and a deficit of women at the bottom. Thus, while men of higher rank received a dowry on marriage, those at the bottom paid bride price to get their wives.

Somewhat surprisingly, however, the modern-day anthropologists tend to dismiss a demographic imbalance in the marriage market as the reason for the growing popularity of dowry marriages (Bhat and Halli 1999). Although a few researchers exposed to the demographic literature

have pointed out its relevance (Rao 1993; Billig 1992; Caldwell et al. 1983), a systematic analysis of the source, size, and trend of the gender imbalance in the Indian marriage market has yet to be undertaken. While it is true that the ratio of males to females in the total population has been steadily rising in India since the beginning of this century, it is important to recognize that women marry at younger ages than men and that in a growing population with a rising annual flow of births, there could still be an excess of women at marriageable ages, because men at older ages are drawn from smaller birth cohorts. Caldwell et al. (1983) were one of the first to suspect the relevance of this phenomenon – known as the “marriage squeeze” in demographic literature – to the growing popularity of dowry marriages in India. Accordingly, marriage squeeze is viewed as the foremost reason for the contemporary marriage practices in India.

Although the imbalance in the gender ratio may explain who gets the rents from marriage, it does not, however, explain the variation in the size of these monetary payments in individual marriages. Moreover, empirical evidence in favor of rising dowries and marriage squeeze, as an explanation for the increase, is both thin and mixed. While early academic accounts by Epstein (1973) and Billig (1992) were based on small sample sizes focused on particular regions of India, the first attempt at providing statistical evidence of dowry inflation, using a sample size of 141 households, was undertaken by Rao (1993). Unfortunately, in later replications of Rao’s results, Edlund (2000) was unable to find support for the marriage squeeze argument. More recent studies, using multiple data sources, have also failed to corroborate the widespread claim that dowry payments have increased in India due to the demographic imbalance in the availability of marriageable brides and grooms (Arunachalam and Logan 2016; Dalmia and Lawrence 2010; Dalmia 2004).

Equalizing Differences

Today the popular view in India is that demographic characteristics of the bride and groom

besides age are the main drivers of the size of dowry and whether it is even paid at the time of marriage. First formalized by Becker (1991), this view is grounded in a model that sees dowry as a spot price that clears the marriage market. In other words, it proposes that dowry constitutes the price of a relevant match that is derived from the individual traits of the bride and groom and their respective households. Thus dowries compensate for bride-groom quality differences and are simply the price of a good match. This also explains the multiple price equilibria observed in the Indian marriage market where dowry varies particularly by sufficient heterogeneity in male attributes.

Rise in importance of education as a determinant of income-earning potential and hence groom attractiveness is considered to account for the increased male heterogeneity. Economic progress and modernization over time has meant that potential grooms are better educated and have more opportunities compared to their fathers (Edlund 2000). This has led to a new criterion for the selection of grooms based upon achieved status. Although women have also experienced generational progress in the realm of education, they have been unable to take advantage of the subsequent employment opportunities (Jakimow 2012). As a result, it is considered worthy to acquire as a son-in-law an educated man who maybe able to occupy a position of power and influence in the organized sector. As the number of such men is limited in relation to the number of girls in the marriageable age, the market forces come into operation and by an informal bidding process, the groom price is settled, giving the community a method of groom allocation among the bidders (Anderson 2003).

That a son’s education will have bearing on his marriage market prospects is an important factor in calculating the returns to educating that son. The expected payoff depends upon the level of investment made in human capital, and the actual outcome for each man depends on how well his family can capitalize on the investment. A related matter is that of underinvestment in daughters. Dasgupta (1993), among others, points to patrilocal marriages – custom in which a married

couple settles with the husband's family – as one source of positive externalities to human capital investment in daughters, making investments in daughters recoupable to a lesser extent than the investment in sons. With limited access to jobs and lack of rights to inherit ancestral or parental property, the bride's household looks for men who can provide security, comfort, stability, and status, which means locating the most well-educated man with the greatest economic potential that one can find (or afford), as given the constraints it seems rational to invest in a share of the grooms prospects.

Moreover, universality and early marriage are two important features of nuptiality in India. There is a strong urgency for women to be married within an acceptable age range, as an unmarried daughter can be a severe economic and social liability to her family. A supplementary reason is the belief in declining fecundity with age. The culturally prescribed necessity for women to marry varies very little with economic, social, and demographic circumstances (Caldwell et al. 1983). Such imperative is evidenced by the fact that 95 % of the Indian women are married by the age of 21 (Goyal 1988). It is said that to a suitable groom a girl should be given in marriage even if she is immature, and if she has attained womanhood her marriage should not be withheld even if the man is unworthy (Sharma 1993). Put together, in the absence of legal or socioreligious compulsions, marrying a daughter off at the cost of dowry must be considered a choice revealed preferred over the alternative of her remaining unmarried and retaining the value of dowry. This indicates that there exist "gains from marriage" for the bride's family, which are at least equal to the value of dowry given.

Furthermore, if the marriage market is competitive with no hidden information, then it may be stipulated that the "gains from marriage" for the bride's family *exceed* any "gains from marriage" for the grooms' family, and it is the net difference in gains that the latter appropriates as dowry. Consequently, in a buyer's market, created by the relative scarcity of a suitable match in combination with strong preference for early, universal and monogamous marriage the subsequent

heightened competition for eligible grooms leaves no alternative but to offer a dowry with one's daughter. Even though the demographic squeeze is resolved through an increase in the average age at marriage of women in the sense that almost all women and men find a mate, the pressures associated with the adjustments in the age difference influence the size of dowries paid (Sautmann 2011).

Empirical work by Dalmia (2004) using retrospective data on marriage transactions collected from 1,878 households in the states of Uttar Pradesh (North India) and Karnataka (South India) provides strong support in favor of the equalizing differences role of dowry payments. Exploiting the critical feature of dowry as a spot price, she regresses dowry on the characteristics of the bride, groom, and their respective households as well as implicit features of the marriage market such as the demographic availability of potential spouses, region, etc. Her results indicate that dowry is a simple economic transaction between two families, functioning to "equalize" the imbalances in the value of marriage. Measurable groom characteristics on which compensating price differentials arise in the study include groom's age at marriage, his education, and height. More recently, Arunachalam and Logan (2016) using retrospective data from the 1996 Matlab Health and Socioeconomic Survey also found strong support for the role of dowries as a price that clears the marriage market in Bangladesh.

Conclusion

Several reasons have been propounded to explain the history of dowry payments in India. These include the form of inheritance system, kinship organizations, individual and household characteristics of the bride and groom, and the demographic availability of suitable grooms in the marriage market. Although rich, academic literature examining the heterogeneity in cultural, demographic, and socioeconomic factors influencing marriage transactions has been unable to completely or sufficiently explain the

prevalence, frequency, and magnitude of dowry payments in India. While lack of availability of representative data on dowries is one reason, the shift in interest to examining the recent trend of rising dowries, referred to in the literature as dowry inflation, is another. Consequently, research on dowry is divided into two lines of exploration. While the first deals with the nature of marriage transactions, the second is focused on the rising value of real dowries that have risen well above a typical bride household's annual income despite the Dowry Prohibition Act of 1961 and its several amendments since.

In summary, while it is impossible to single out a set of factors that can explain the incidence and spread of dowry payments in India, this key idea allows us to at the least systematically examine the different theories and explanations that populate the literature on marriage transactions in the country. Further research on the two main motives suggested by researchers for the prevalence and escalation of dowries, a bequest versus a price for a good match is crucial if we are to suggest effective policy recommendations that will help curb the spread and growth in dowry payments across India.

Bright Male Hypothesis

Anders Pape Møller
 Ecologie Systématique Evolution, Université
 Paris-Sud, CNRS, AgroParisTech, Université
 Paris-Saclay, Orsay, France

Synonyms

Intersexual selection; Mate choice

Definition

The bright male hypothesis is defined as intersexual selection (i.e., mate choice by the choosy sex, or both sexes), resulting in the evolution of extravagant secondary sexual characters that depend on which communication channel is used and that either reveal material or genetic benefits for the choosy individual.

Introduction

The bright male hypothesis suggests that specific features of male quality reliably reflect underlying benefits that individuals of one sex (usually females) may acquire from their mate choice. The underlying benefits acquired through mate choice may either be material or genetic (Andersson 1994). Material benefits may include among others a territory of superior quality, sperm of superior fertilizing ability, or a partner providing superior courtship food for the female or parental care of superior quality or quantity (Andersson 1994). Mate choice may occur among individuals of the choosy sex, usually females, but mutual sexual selection in the two sexes is also common although rarely of a similar strength in males and females. Such mate choice may occur before and/or after copulation (i.e., pre- or postmating sexual selection).

The bright male hypothesis accounts for the evolution of numerous characters that have evolved beyond the exaggeration expected under natural selection. Already Darwin (1871) provided a long list of such characters in animals, but also in humans, emphasizing the importance of direct fitness benefits, while Wallace (1889) emphasized the importance of interspecific interactions, in particular predation and parasitism, for the evolution of brightness that reflected what subsequently became known as the “good genes” hypothesis.

How can reliability of the content of sexual signals involved in signaling male brightness be enforced? The handicap principle provides a general solution to this problem by suggesting that only individuals in prime condition are able to

develop and maintain the most exaggerated secondary sexual characters because individuals in poor condition pay a disproportionately large cost for producing their secondary sexual characters (Zahavi 1975). In other words, it is the condition-dependence and the differential cost of large displays that prevent males with inferior quality. Condition in this context can be caused by resistance, amounts of essential reserves (such as antioxidants), or maternal effects transmitted to the developing egg or embryo. The handicap mechanism may work at a number of different levels. One particular mechanism is the immunocompetence handicap that arises as a result of negative effects of hormones, in particular testosterone, as a suppressor of immunity (Folstad and Karter 1992). Such immune-suppression may lead to a trade-off between efficient immunity on the one hand and high levels of sex hormones that underlie the physiological mechanisms producing secondary sexual characters or sexual behavior on the other.

Components of the Bright Male Hypothesis

The bright male hypothesis can be split into different component parts depending on the communication channel (vision, sound, smell etc.) and depending on the underlying selective agents (be they parasites or predators, for example) and the resulting sexual displays and the assessment of such displays. Ryan and Keddy-Hector (1992) have shown for secondary sexual characters that independent of communication modality individuals with the most exaggerated characters are the ones that are most preferred. This deviates strongly from contact signals such as those used for maintaining contact between individuals or for predator-prey signaling. The evolution of exaggerated secondary sexual characters can also be seen as the coevolution of signaler and receiver including the sense organs used for assessment of signals. In other words, the basis for Darwinian esthetics is sexual selection and the biology of beauty (Grammer et al. 2003).

Secondary sexual characters may be purely attractive without any other specific signaling content (Fisher 1930). This so-called sexy son mechanism implies that choosy females benefit from their mate choice through the sexual attractiveness of their sons and hence mating success in the subsequent generation and the female mate preference of their daughters. While the sexy son hypothesis is affected by mate choice, there is no specific functional benefit of mate choice except for the advantages of heritable sexual attractiveness across generations. In this way, the sexy son hypothesis differs from the other functional hypotheses by not providing material benefits or genetic benefits beyond pure attractiveness. In real life, the Fisher mechanism and the other mechanisms of mate choice are likely to represent continuous gradients rather than distinct classes of benefits.

The bright male hypothesis can also be taken literally to represent the coloration or the brightness of the skin reflecting the condition or the health status of an individual. Studies of humans have shown that the color of the skin but also its texture reliably reflects the health status of the signaling individual human (Fink et al. 2001, 2006; Grammer et al. 2003). In particular, interactions between sex hormones and microorganisms seem to determine the condition of the skin, implying that individuals with specific hormonal profiles affect the composition of the microorganisms of the skin. This interaction between humans and microorganisms of the skin is particularly prominent during puberty, when increasing levels of sex hormones affect interactions between humans and microorganisms.

The so-called microbiome is the community of microorganisms that live on and within all living organisms. The average human harbors several kg of microorganisms, mainly bacteria and fungi (Turnbaugh et al. 2007). The microbiome has been implicated in a large number of medical conditions including cancers, stomach problems, and obesity. A number of diseases that correlate with the composition of the microbiome leaves open the possibility that mate choice and the brightness of sexual displays reflect not only the condition of the individual human, but also the

interaction between humans and the underlying microorganisms that constitute the microbiome. Studies of birds have shown that secretions from the uropygial glands that constitute important antimicrobial defenses employed to the plumage and the skin also increases the brightness of the plumage as seen by conspecifics and heterospecifics (e. g., Surmacki and Nowakowski 2007).

Parasites constitute important selective agents affecting viability and reproduction of their hosts. For example, many more humans have been killed or otherwise negatively affected by parasites than by predators, and hence parasites constitute an important selective pressure affecting all living beings including humans. Even today millions of humans die due to infectious disease. Some estimates have suggested that more than half of all species are parasites. Therefore, the bright male hypothesis may rely on the important selection pressure derived from parasites. If sexual signals develop and are maintained under the influence of parasitism, then sexual signals may either reflect genetically based parasite resistance, parenting ability, or the risk of sexually transmitted disease.

Superior ability to avoid predation may constitute another basis for the evolution of extravagant secondary sexual characters (Wallace 1889). If the expression of secondary sexual characters reflects the ability to perform strenuous exercise, individuals with exaggerated secondary sexual characters should also have superior ability to escape from predators. Furthermore, predators should learn through repeated exposure to prey that prey individuals in poor condition will have the palest coloration and be the least bright. Hence, learning should reinforce the reliability of secondary sexual characters as reliable indicators of condition, and prey may start signaling their superior ability to evade escape (Cott 1947). Predation is the second-most important interspecific interaction after parasites that results in the second-largest number of deaths among free-living organisms. However, it seems unlikely that humans have suffered from high mortality caused by predators during recent evolutionary history.

Superior antioxidant status may also affect sexual displays (von Schanz et al. 1999). All metabolic processes result in the production of free

radicals that can interact with DNA and other molecules but also with surface proteins and thereby cause damage that if left on its own without repair would result in reduced performance. DNA damage if not repaired results in mutations that can reduce performance of the soma in the current generation, or if affecting gametes can result in reduced performance of offspring in the next generation due to the generally slightly deleterious effects of mutations. Free radicals can be neutralized by antioxidants such as vitamin A and E, carotenoids and intracellular antioxidants such as glutathione that generally are ingested in the diet. They are often in short supply as shown by many studies demonstrating increased performance with increased supplementation of antioxidants, but also from the preference of animals including humans for food with high antioxidant levels. Individuals may differ in their use of antioxidants, for example, because the production of immune cells such as lymphocytes results in production of free radicals, or because a high diversity of alleles of the major histocompatibility complex results in lower levels of disease and hence production of fewer lymphocytes. Finally, antioxidants and carotenoids may act as molecules stimulating the immune system and thereby reliably reflecting health status (Møller et al. 2000).

Sex differences in brain size and superior cognitive abilities have been suggested to play a role in sexual selection (Miller 1993). Indeed, larger brains in men than in women have been associated with different components of sexual behavior in humans (Miller 1993). While protean courtship behavior may account for the evolution of sexually dimorphic brains in humans, this seems unlikely to be a general explanation because sexually size dimorphic brains also have evolved in numerous other organisms that indicate an ancestral state of sexually dimorphic brains that predates humans and apes. Different species differ in their sex difference in brain size, begging the question whether such sex differences may play a role in sexual selection. Bird species in which males produce more complex songs tended to have larger sex differences in overall brain size (Garamszegi et al. 2005a). Furthermore, bird

species in which females have relatively larger brains than males have a higher degree of extra-pair paternity (Garamszegi et al. 2005b). Thus, the evolution of sperm competition may select for complex behavior and the underlying neural tissue in the sex that has superior ability to control extra-pair copulations. Preliminary intraspecific studies in birds have suggested that brain size accounts for social and sexual behavior such as arrival date, flight performance, defense of offspring, and social competition (Møller 2010).

Sperm from different males but also from different species differ in locomotory ability, morphology, and surface immunological properties, and these differences can be linked to the frequency of extra-pair copulations and competition for paternity (Birkhead and Møller 1998). Multiple paternity or extra-pair paternity are common in many different organisms including humans (mean frequency of extra-pair paternity in humans is approximately 10 % of children). Such a high level of extra-pair paternity has selected for pre- and postcopulatory paternity defenses such as mate guarding, retaliatory copulations, sperm with superior swimming ability, allocation of sperm to coincide with the timing of fertilization, and selection for sperm morphology that results in superior fertilizing ability (long flagellum and large mid-piece of the head of sperm containing more mitochondria that facilitate sperm movement). Sperm have immune receptors that allow for assessment of immunoglobulins in the seminal fluid and in the female reproductive tract, and such effects may have consequences for sperm motility and hence for fertilizing ability.

Superior genes include so-called good genes or complementary genes. The so-called good genes hypothesis is based on the assumption that males with extravagant displays reveal their underlying genetic constitution and only males with this constitution are able to produce the most extravagant secondary sexual characters. Such good genes can be passed on to the next generation through female choice of sperm and hence fertilizations. A meta-analysis of good genes sexual selection revealed a small, but statistically significant effect size among animals including humans implying that females through their mate choice can

significantly increase the viability of their offspring (Møller and Alatalo 1999). Hamilton and Zuk (1982) suggested that parasites may provide a particularly likely mechanism accounting for good genes because continuous coevolution between hosts and parasites can maintain genetic variation in resistance. In each generation, individuals with novel genotypes will be able to resist most of the parasites and hence be able to produce the costliest and most exaggerated secondary sexual characters. An alternative mechanism relies on complementarity of genes of females and their male partners so that only offspring with complementary genes due to different alleles obtained from the mother and the father will be able to produce the most exaggerated secondary sexual characters (Roberts and Little 2008). Thus, partners with different alleles will show the highest level of resistance. A potential example of such complementary alleles is the major histocompatibility complex (MHC) that is involved in production of a high level of diversity of resistance alleles in numerous organisms including humans. Studies of humans have also shown links between MHC diversity and attractiveness of potential partners (Thornhill et al. 2003; Garvar-Apgar et al. 2006).

Developmental instability may play a role in the bright male hypothesis. Developmental instability reflects the inability of an individual to produce a regular and symmetric phenotype under given environmental conditions (Møller 1990). Secondary sexual characters have higher levels of bilateral asymmetry than other morphological characters, and in many species males with the largest secondary sexual characters also produce the most symmetric secondary sexual characters (Møller et al. 1998). Because there is a small heritability of asymmetry, but a large component of additive genetic variance (Van Dongen and Gangestad 2011), females mating with males with the largest, but also the most symmetric secondary sexual characters will produce offspring with superior symmetry. Studies of humans generally show preferences for symmetric individuals, and a number of studies have linked such preferences to other preferred traits such as faces, bodies, and smells.

Male and female parental care occurs in many organisms including humans. This is the most obvious (and almost trivial) mechanism accounting for the evolution of extravagant secondary sexual characters. Since it is costly to produce and maintain such extravagant characters, only individuals in prime condition will be able to also provide significant amounts of paternal care (Hoelzer 1989). Surprisingly, the expression of secondary sexual characters is a poor predictor of the amount of paternal care in taxa as diverse as insects and birds (Møller and Jennions 2001). In fact, in bird species with a high frequency of extra-pair paternity, males provide little or no parental care, while male care is more extensive in species with little or no extra-pair paternity (Møller and Thornhill 1998). These findings are consistent with the hypothesis that male care is uncommon in species with a high level of “good genes” sexual selection, but rare in species with little or no “good genes” sexual selection. This negative relationship between frequency of extra-pair copulations and the extent of male parental care is paralleled by results from analyses of male parental care and extra-pair copulations in humans (Gangestad and Thornhill 1997).

Conclusion

The bright male hypothesis concerns the mechanisms and the function of secondary sexual characters involved in intersexual selection, i.e., mate choice. A number of different mechanisms and functions have been proposed, but their relative importance and merit in human studies largely remain unresolved.

Broca's and Wernicke's Aphasia

Juliana V. Baldo¹ and Nina F. Dronkers²

¹Veterans Affairs Northern California Health Care System, Martinez, USA

²University of California, Davis, CA, USA

Synonyms

Fluent aphasia; Motor aphasia; Non-fluent aphasia; Sensory aphasia

Definition

Broca's aphasia is a speech and language syndrome caused by brain injury that is characterized by an impaired ability to speak fluently but with relatively intact language comprehension. In contrast, Wernicke's aphasia is a syndrome characterized by difficulty in comprehending language, with relatively fluent speech that contains paraphasias and errors in word choice.

Introduction

Speech and language disorders arising from brain injury, known as “aphasia,” have long been recorded in human history. The terms “Broca's” and “Wernicke's” aphasia were named after two nineteenth century European neurologists, Pierre Paul Broca and Carl Wernicke, who carefully documented and characterized distinct aphasia syndromes. Broca was a French neurologist who was involved in a debate about the localization of the seat of human speech in the brain. A series of cases, including a famous patient “Tan” who could say very little other than the syllable “Tan,” led Broca to declare that speech production was associated with a specific region in the left hemisphere of the brain, the posterior inferior frontal gyrus, which came to be known as “Broca's area.” Despite their difficulty in

speaking, these patients exhibited relatively good language comprehension, and the syndrome was later termed "Broca's aphasia." Subsequent studies have shown that the areas affected in Broca's aphasia include additional gray and white matter structures in the left hemisphere beyond the inferior frontal gyrus.

A few years later, Wernicke studied and described another group of patients in which a reverse pattern of speech and language was observed, namely, extremely poor language comprehension but relatively fluent speech production (albeit with word choice and semantic errors). This pattern of language deficits was then subsequently called "Wernicke's aphasia." Based on his findings, Wernicke identified regions in the posterior part of the left hemisphere that he believed to be critical for language understanding, and this general area of left temporoparietal cortex came to be known as "Wernicke's area." As with Broca's area, subsequent research has redefined the extent of posterior cortex subserving language comprehension to include additional areas such as the left posterior middle temporal gyrus and superior temporal sulcus (Dronkers and Baldo 2009).

The question for evolutionary psychologists and biologists is to what extent and at what point in evolutionary history did these speech and language functions and their underlying brain regions evolve to subserve these specific linguistic processes. Unlike some aspects of human evolution, there is no physical trace left with respect to the evolution of language, which must instead be inferred based on other types of information, such as data from comparative studies.

Comparative Anatomy of Speech and Language

Human brains are approximately three to four times larger than what would be expected for a primate of our size. It has been suggested that the reason for this disproportionate growth is the emergence of language. In support of this supposition, human neocortex is specifically enlarged in left prefrontal and posterior temporoparietal cortices (Rilling 2014; but see Hopkins et al. 2016). It

is thought that these expanded zones in humans enabled associations to be formed across sensory modalities (e.g., to associate auditory with visual stimuli so that naming objects became possible). Whereas in "lower" mammals primary sensory cortex connects more directly with brain regions that induce an automatic motor response (e.g., fleeing from a predator), multimodal association areas in humans allowed for higher-order cognition including language.

In addition to the disproportionate expansion of language zones, another argument for the specialization of language in the human brain over the course of evolution is the fact that these brain regions are primarily lateralized to the left hemisphere. The right hemisphere homologues of Broca's and Wernicke's area do not typically result in speech and language impairments. In humans, Broca's area is both larger overall and is disproportionately larger in the left hemisphere, relative to our closest relative, the chimpanzee. Using MRI to compare Broca's area in humans and chimpanzees, Schenker et al. (2010) found similar cytoarchitecture across the two species, but, unlike in humans, Broca's area in chimpanzees did not show a leftward asymmetry. In terms of posterior language regions, the planum temporale, a portion of Wernicke's area in the superior temporal plane, is also larger in the left hemisphere in chimpanzees as it is in humans (Gannon et al. 1998); however, Wernicke's area proper appears to be, like Broca's area, disproportionately enlarged in the left hemisphere in humans (Schoenemann 2009). Interestingly, a more recently identified region critical to human language comprehension, the left middle temporal gyrus, does not exist in monkeys.

More recent comparative work has focused on the fiber pathways, or white matter, that connect critical language zones in the brain. It has been shown that the disproportionate growth in the human brain is due in part to the expansion of neural connectivity as measured by greater white matter volume (Hopkins et al. 2016; Rilling 2014). Using MRI techniques such as diffusion-weighted imaging and diffusion tractography to measure white matter, Rilling recently compared the brains of humans, chimpanzees, and rhesus

macaques and showed that a critical language pathway in the human brain known as the arcuate fasciculus has a “massive” projection beyond Wernicke’s area in the superior temporal/inferior parietal cortex and into the left middle and inferior temporal gyri (Rilling 2014). This projection was much more extensive in humans than the arcuate projection in nonhuman primates and monkeys. The targets of this brain pathway are known to be critically involved in processing word meaning and, when damaged, result in chronic Wernicke’s aphasia in humans (Dronkers and Baldo 2009).

Evolution of Motor Speech and Language Behaviors

Forms of communication, such as processing species-specific calls, have been associated with both Broca’s and Wernicke’s area homologues in monkeys (Gil-da-Costa et al. 2006). Taglialetta et al. (2008) used positron emission tomography (PET) to show that when chimpanzees signaled for food, the left inferior gyrus (part of Broca’s area) was activated, along with a few other cortical and subcortical sites. However, unlike humans, these regions are not indispensable, for example, lesions to Broca’s area homologue in monkeys do not interfere with vocalization (Kirzinger and Jürgens 1982). In a comparative fMRI study, a portion of Wernicke’s area (the superior temporal sulcus) showed specialization in humans, but not monkeys, with respect to responding to species-specific vocalizations (Joly et al. 2012).

Very specific vocalizations are present in non-human primates as well as other mammals and birds. However, much of these motor speech abilities in other species are mediated by subcortical structures that mediate automatic (i.e., instinctive) vocalizations. In terms of more voluntary motor speech acts, Broca’s area and surrounding regions appear to be critical in humans and possibly chimpanzees (Rilling 2014).

It is thought that perhaps that Broca’s area in humans evolved from an antecedent that subserved imitation. So-called “mirror neurons” in the brain have been identified in Broca’s area (homologue) in monkeys; these cells respond similarly when an

animal performs an act (e.g., reaching for an object) as when the animal *observes* another animal perform the same act (e.g., another monkey reaching for the object; see ► [Mirror Neurons](#) in this volume). Such mirror neurons have been suggested as a possible mechanism allowing for the subsequent evolution of language in humans.

Taken together, these findings suggest that more voluntary, complex language production and comprehension that characterizes human language is mediated by specialized regions in the left hemisphere and that these regions likely evolved from bilaterally mediated brain regions that subserve more basic forms of communication in other mammals.

Conclusions

There is substantial evidence from comparative studies that specialized brain regions known broadly as Broca’s and Wernicke’s area subserve complex speech and language behaviors in primates, reaching their zenith in humans. When these brain areas are damaged in humans, individuals can exhibit relative difficulty with speech production or language comprehension, disorders known as Broca’s and Wernicke’s aphasia, respectively. However, there is still considerable debate as to whether these specialized neural/cognitive structures that subserve speech and language evolved specifically for communication or whether they evolved from preexisting brain/cognitive structures that subserve other functions related to conceptual understanding. As Schoenemann (2009) states, “To the extent that a particular area known to be relevant to language appears to have also changed significantly, we are justified in inferring that this area was important for language evolution,” but he also cautions “whether [the brain area] increased specifically for language will be difficult to determine.” Moreover, Schoenemann argues that not only do we need to understand how the brain evolved to better support language in response to selective pressures related to social communication but also how cultural transmission of language adapted based on the constraints of the human brain.

Definition

In humans, two regions in the left cerebral hemisphere linked with the production and comprehension of speech.

Introduction

Paul Broca (1824–1880) and Karl Wernicke (1848–1905) were European physicians working in the late nineteenth century with patients with brain damage. Broca (1861a, c) described patient Leborgne (and a later, similar patient, Lelong; Broca 1861b) who was unable to produce any fluent speech, with relatively intact comprehension of what was said to him. His brain damage was largely restricted to the inferior frontal gyrus of the left hemisphere. Wernicke (1874) described a series of cases who presented with an apparently opposite pattern: poor comprehension of speech, with relatively intact abilities to produce speech sounds (although what was produced was often difficult to comprehend). These patients had lesions in more posterior regions of the superior temporal gyrus in the left hemisphere. These observations spawned many efforts to establish localization of function in the human brain, an idea that had been largely dismissed, thanks to the worst excesses of the nineteenth-century phrenology. These pioneering studies also introduced the idea of

hemispheric specialization for language. Subsequently, primatologists and comparative psychologists have worked tirelessly to try to establish the existence/extent of, and asymmetries in, homologous regions in language-lacking nonhuman primates (the great apes in particular), but some of the claims are not without controversy.

Functional Localization and Hemispheric Specialization: The Dysphasias

The work of Paul Broca, Karl Wernicke, Marc Dax, and others such as Lichtheim, spawned one of the first “growth industries” in what would, in the subsequent century, become cognitive neuroscience. Broca’s contribution was primarily to link a serious acquired language disorder (which he originally referred to as *aphemia*, “without speech,” which would later become known as *aphasia*) with a lesion of the inferior frontal gyrus (Broca 1861c). This work reinvigorated the search for functional localization in the brain. A few years later (presented in 1863, published in Broca 1865), he was to note how a series of cases with aphasia all had damage to the left hemisphere. This observation spawned innumerable experiments and theories for documenting and understanding these and related asymmetries in humans and helped to create a similar effort in nonhuman animals which continues to this day.

A decade after Broca’s work on this theme, Karl Wernicke (1874) distinguished “motor” types of aphasia (similar to the nonfluent aphasia that Broca had described) from more sensory types; localized these to anterior and posterior sectors of cortex around the Sylvian fissure, respectively; and documented that the quite fluent type of aphasia most frequently was a consequence of damage to the left superior temporal gyrus. It was Wernicke who made the most of the motor-sensory distinction between anterior and posterior types of aphasia and not Broca as some people erroneously believe. The

confused-sounding jargony speech, later referred to as a “word salad,” of patients with more sensory types of aphasia (which have since become known as Wernicke’s aphasia), could be easily misdiagnosed as some sort of confusional/demented state; Wernicke correctly understood it as a disturbance of language (Wernicke 1874).

Wernicke was heavily influenced by the ideas of Meynert and emphasized that many higher linguistic processes would not be easily associated with specific regions of the brain but emerged from the anatomical connections of a limited number of circuits between regions with specialized functional roles. These ideas reveal considerable foresight, considering the popularity of studies of human and nonhuman “connectomes,” now studied using magnetic resonance techniques such as diffusion tensor imaging.

After these sets of observations, inspired by Broca and Wernicke, work on classifying subtypes of speech and language disorder and linking them to anatomy led to an explosion in simple box and arrow diagrams of speech and language subprocesses and how they could be selectively affected by damage to different parts of the left hemisphere. “Aphasiology” was born, and for a period of about 50 years, classifications and subclassifications proliferated uncontrollably. “There are almost as many classifications of aphasia as there are aphasiologists,” (Bogen and Bogen 1976, p. 834). In spite of these excesses, an early form of cognitive neuroscience, alive and well today, was born.

This posterior comprehension, anterior production view of speech in the left hemisphere has dominated thinking in aphasia, linguistics, and behavioral neurology. More recently, in part due to the revitalizing efforts of Norman Geschwind (e.g., Geschwind 1970), it has been reenergized, albeit with a few transformations driven by a series of important caveats (Poeppel and Hickok 2004). These include, for example, rethinking of the specific deficits in so-called conduction aphasia, caused by lesions of the major nerve fiber pathway connecting Wernicke’s and Broca’s regions.

A Structural Marker for Language Areas?

In human beings, the eventual definitions of Broca's and Wernicke's areas were born out of the association of a particular type of speech or language deficit with a relatively circumscribed, specific lesion in the left hemisphere. Subsequent attempts to generate nonhuman animal models of "language"-like processing can rather stretch analogies of how vocal communication systems in nonhuman primates map onto the intricate linguistic nuances of human language (Gil-da-Costa et al. 2006; see also 'Language Preadaptations' in this Encyclopedia). Even so, such studies in nonhuman primates have, in part, contributed to the idea of a Wernicke's area in humans becoming somewhat controversial, mainly due to data from nonhuman animals and neuroimaging in humans which imply that more anterior regions of the temporal lobes are much more important than posterior regions for conspecific vocalizations and for word meaning and semantics (De Witt and Rauschecker 2013). This controversy is in stark contrast to the scientific fate of Broca's area, where most scientists tend to agree on the broad brushstrokes of its location (albeit with considerable debate about its precise functions; Grodzinsky and Amunts 2006). Broca's area in humans is quite routinely linked with putative homologues in nonhuman animals, thanks in part to the popularization of the mirror neuron doctrine which came into its own in the 1990s and early 2000s.

An additional problem for the idea of a defined, specific region for Wernicke's area is that neurologists and aphasiologists have deviated from the original claim about a region important for speech comprehension, thought to be "the superior temporal gyrus" by Wernicke (1874), into (1) a more circumscribed posterior temporal region, synonymous with the planum temporale (a triangular region in the posterior part of the superior temporal gyrus, just posterior to the "transverse gyrus of Heschl"); (2) to an even smaller region called TpT in nonhuman animals (Galaburda and Sanides 1980); or (3) to a much larger region than Wernicke suggested, also including the middle temporal gyrus, parts of the inferior temporal

sulcus, and more ventral regions of the angular and supramarginal gyri in the inferior parietal cortex (Bogen and Bogen 1976).

In spite of these discrepancies in localizing these regions in human beings, the popularization of magnetic resonance imaging for producing structural images in living human and nonhuman animals led to an explosion of comparative work on putative Wernicke's and Broca's regions. In humans, the original focus was on identifying a structural marker of underlying cerebral asymmetry for language, and thanks to Geschwind and Levitsky (1968), an attractive candidate was identified: the planum temporale, which was larger in the left hemisphere in 65 of 100 human postmortem brains. As is often the case, the original excitement about a structural marker of underlying function soon fell from favor for several reasons, including methodological arguments about how to define the planum (particularly with other structural asymmetries affecting its borders); the recognition that the leftward structural asymmetry, however defined, was not common enough to be a robust marker of leftward language dominance (over 90%, estimated by several different methods – Carey and Johnstone 2014); and poorer than hoped for inter-rater reliabilities (Dorsaint-Pierre et al. 2006; Dos Santos Sequeira et al. 2006). Having said that, these studies went some way toward identifying the degree and extent of intersubject variability and how that might inform necessary sample sizes, a question less frequently addressed in some of the cytoarchitectonic and comparative studies that followed.

The Evolution of Broca's and Wernicke's Regions: Do Nonhuman Species Have Cortical Regions That Are Homologues?

Comparative psychologists and primatologists, since the time of Darwin, have often focused on how nonhuman primates in particular compare with human beings on a number of dimensions related to what might loosely be referred to as "intelligence." It was fairly simple for these researchers to extend these explorations to brain structures in our closest cousins, in parallel with

efforts to explore the proto-linguistic capabilities of gorillas, chimpanzees, and latterly, bonobos. In fact, the anatomists anticipated these later twentieth-century trends, by using microscopic techniques in small numbers of monkeys, chimps, and humans, in efforts to establish similarities among, and differences between, primate species, particularly in terms of the structure of the cerebral cortex (see also 'Language Preadaptations' in this Encyclopedia). These approaches emphasize careful identification of borders between zones of cortex, based on the characteristics of cells (i.e., the cell architecture or "cytoarchitectonics"), seen in stained sections of postmortem brains.

One limitation of this approach, often forgotten, is that some of the earliest classic cytoarchitectonic studies, frequently cited today as evidence for cross-species homologies, were in fact designed to label subregions of the human brain using the same nomenclatures as those developed earlier in, most frequently, the brain of the Macaque or Rhesus monkey (e.g., Galaburda and Sanides 1980). The more popular version of Brodmann's map, for example, does exactly that (Zilles and Amunts 2010). Many of the later attempts at labeling cortical subregions in nonhuman animals are in fact based on one or two of the nomenclatures available from the early twentieth century, such as that devised by Brodmann (Šimić and Hof 2015), which themselves were often based on rather subjective decisions on borders and boundaries, made from observations of small numbers of human (and nonhuman) brains.

Although a few previous attempts had been made to identify Broca- or Wernicke-like regions in nonhuman animals, a mention in a seminal neurophysiological paper published in 1996 (Gallese et al. 1996) has been particularly influential to date, partially due to the elegant demonstration of single neurons that increase their firing rates when a monkey performed a specific act or observed another agent performs the same act. These cells, referred to as "mirror neurons," have led to an explosion of work on perception-action associations in human and nonhuman animals. Much of the furore that followed depended, in part, on the claim that the region in the Macaque

brain ("F5") which contains many of the mirror neurons was a "homologue" of Broca's region. Tentative comparisons in original sources have become reified in subsequent "nests" of citations that claim homology for human and monkey or great ape Broca's regions, most rather far removed from the original cytoarchitectonic and anatomical evidence on which they are ultimately based.

A further development in the comparative literature on Broca's and Wernicke's areas is the appearance of studies which claim leftward asymmetries in nonhuman animals for the target regions, clearly an analogy to the functional asymmetries described in patients by aphasiologists. Although Geschwind himself could not find good evidence for an asymmetry of the planum temporale in chimpanzees (LeMay and Geschwind 1975), Gannon et al. (1998) did so, using fixed brains for measuring the volume of the planum in a sample of 18 chimpanzees. They found leftward asymmetry in a remarkable 17 of them. That this asymmetry was considerably larger than that claimed in human samples has not gone unnoticed (e.g., Tervaniemi and Hugdahl 2003), yet this potential caveat has had little effect on the enthusiasm for this type of comparative structural work. Subsequent reports have argued for, for example, asymmetries in Wernicke's area assessed using a different method than used by Gannon and collaborators (Hopkins et al. 1998), as well as asymmetries in a premotor region claimed to be Broca's area (not entirely synonymous with the F5 of mirror neuron fame; Cantalupo and Hopkins 2001).

In spite of the caveats, many studies have moved on from these descriptions of Broca and Wernicke area homologues in nonhuman primates, to attempt to relate these structural asymmetries to behavior (e.g., Taglialetela et al. 2008). For example, Cantalupo et al. (2009) argue that asymmetries in white/gray matter ratios favor the left hemisphere on average, in a sample of 33 chimpanzee MRI scans. They also found statistically significant relationships between these measures and gesture bias (extended arm movements from the home cage begging for food), although oddly the "non-right-handed" group showed greater

leftward white to gray matter asymmetry in the frontal lobes than the right-handed group. More recently, detailed analysis of the cortical thicknesses of a sample of chimpanzees relative to humans was performed. Among a number of statistically significant findings, in spite of significantly greater gyrification in humans (particularly in Broca's region as compared to its putative chimpanzee homologue), asymmetries between left and right hemispheres were similar in the two species (Hopkins et al. 2016).

Many of the papers arguing for similarities of human and nonhuman primate brains come from one or two research groups, particularly prolific in this field and that of nonhuman primate handedness, for which they are similarly oriented. These questions can become somewhat politicized, as for some scientists arguing against human uniqueness in some evolutionary sense is an important part of their scientific agenda (Preuss 2006). Even so, biologists who are not primatologists (e.g., Vallortigara et al. 1999), as well as neuropsychologists, argue that being *unable* to contextualize human asymmetries of language (and handedness) in broad evolutionary terms would undermine the biological underpinnings of cerebral asymmetries of regions such as Broca's and Wernicke's (e.g., Corballis 2012). Of course, our last common ancestor with the great apes last walked the earth 6–10 million years ago; evolutionary changes that capture some of our species' apparent uniqueness must exist and be distinct from the other great ape species (who have also been evolving for the same period of time, in spite of a surprisingly scant archeological record of it. As intriguing as these comparisons are, a more careful appraisal of the anatomical and functional evidence claiming homologues of Broca's and Wernicke's area in nonhuman species is warranted.

Conclusion

Broca's and Wernicke's regions in the left hemisphere of humans have been identified, somewhat prematurely, with speech production and comprehension, respectively. Modifications of this model

have not changed the consensus regarding left hemispheric "dominance" of these regions, even though investigators argue about their precise extent, location, and function. Although behavioral asymmetries in other species are not uncommon, the strongest claims for regions akin to Broca's and Wernicke's area are in the nonhuman great apes, such as chimpanzees. In fact, asymmetries in these regions, however defined, have been reported for a number of different structural and morphological features, and they have been related to behavioral asymmetries in the same nonhuman animals. Nevertheless, issues of statistical power and precision remain underexplored in some of the human work on molecular architecture, which makes some of the claims of Broca's and Wernicke's homologues difficult to extensively and exhaustively evaluate.

Definition

Brodmann has subdivided the cerebral cortex into areas, based on differences in the cellular architecture, i.e., cytoarchitecture (Brodmann 1909a). These areas were later called “Brodmann areas.”

used as a reference of the brain’s microstructure for interpreting results of neuroimaging studies. However, more recent studies have shown that this map does not hold true in many brain regions, and alternative mapping strategies and new maps have been proposed (Zilles and Amunts 2010).

Introduction

Starting from the beginning of the twentieth century, the German neurologist Korbinian Brodmann (1868–1918) published several papers on the cellular architecture of the cerebral cortex in the human brain and a highly influential monograph in 1909 (Brodmann 1909a). The monograph was later translated to English (Brodmann 1909b). Brodmann showed a schematic map of the cerebral cortex including 43 cortical areas, belonging to 11 regions (Fig. 1). This map is still

Methodical and Technical Basis

Brodmann observed differences in the architecture of cells such as the presence of special cell types (e.g., Betz cells in the primary motor cortex, BA4), the type of the laminar pattern, the visibility of cellular columns, and other features in cell-body stained histological sections of a human brain hemisphere. He studied horizontal sections, and the first area that appeared in the most dorsal horizontal section was labeled as area 1; later areas got higher numbers.

Brodmann Areas, Fig. 1 Brodmann map, lateral view; areas are labeled by numbers (Brodmann 1909a)

Discussion of the Concept of Brodmann Areas

Although not proven at that time for the vast majority of areas, Brodmann was convinced that every cortical area supports a certain function. While the assumption of such relationship was straightforward, e.g., for primary motor (BA4) and primary sensory areas (e.g., BA17, primary visual cortex), it could not be proven for areas involved in higher cognitive functions at that time.

Recent studies in brains of animals, lesion and neuroimaging studies, demonstrated that Brodmann's map is incomplete or even wrong in some of the brain regions. For example, his tripartition of the visual cortex is in contrast to more recent findings indicating the presence of more than a dozen of visual areas.

A major problem of his mapping approach is the lack of information concerning intersubject variability and interhemispheric differences. It is known today that cortical areas of individual brains differ significantly in size, localization, and shape. Another point of criticism relates to the definition of borders between cortical areas based on pure visual inspection. This led to discrepancies with maps from other authors, e.g., those of von Economo and Koskinas and the map of the Russian school; for a review see, e.g., (Zilles and Amunts 2010).

Recent Mapping Strategies

Observer-independent methods have been developed to achieve a reproducible and reliable identification of borders between cortical areas (e.g., Schleicher et al. (2005)). Intersubject variability in brain structure is captured by probabilistic maps, indicating the probability of an area in standard stereotaxic space (Mazziotta et al. 2001; Roland and Zilles 1994). For example, the JuBrain Atlas (Fig. 2) contains probabilistic cytoarchitectonic maps, where borders of areas have been identified based on image analysis and statistical criteria in histological sections of ten postmortem brains; these individual maps were superimposed in standard reference space,

Brodmann Areas, Fig. 2 Maximum probability maps (MPM) of the JuBrain atlas (<https://www.jubrain.fz-juelich.de/apps/cytoviewer/cytoviewer-main.php>) and available through the collaboratory of the Human Brain Project (<https://www.humanbrainproject.eu/en/>). They are part of the SPM toolbox (Eickhoff et al. 2005) and other software packages. Mapping is based on an observer-independent method for the definition of borders in serial histological sections of ten postmortem brains (Schleicher et al. 2005). The MPM assigns each voxel of the reference space to that area, which showed the highest probability at that position (Eickhoff et al. 2005)

and probabilistic maps have been calculated (Amunts and Zilles 2015). An *in vivo* based parcellation of the cerebral cortex has been provided using multimodal magnetic resonance images from the Human Connectome Project (HCP) and an objective semiautomated neuroanatomical approach (Glasser et al. 2016). Another example of a human brain map comes from the Allen Brain Institute, integrating anatomic and genomic information (Hawrylycz et al. 2012). Multimodal and multilevel mapping approaches have been proposed to integrate the different aspects of brain organization. For a recent overview and more atlas tools see (Amunts and Zilles 2015).

Recent Understanding of Cortical Areas

It is well accepted that the cerebral cortex is composed of areas, which are characterized by a certain microarchitecture, gene expression pattern, molecular architecture connectivity, and brain function.

Various cortical maps and parcellation schemes have been forwarded, which differ in the number of areas, their ontology, and the aspect(s) of brain organization that they reflect, e.g., cytoarchitecture, connectivity, multi-modal. How the different parcellations are related to each other is an ongoing field of research. The description of human brain organization requires more than one map, which form an atlas.

Conclusion

Brodmann areas represent an important step in the history of neuroscience, but do not reflect the state of the art of cortical parcellation. The knowledge about microstructurally defined cortical areas is more than just to provide “labels” – these areas are necessary to understand brain organization and to relate brain functions to the underlying microstructure on a sound biological basis. To cover the whole network, cortical maps have to be combined with maps of subcortical nuclei. Cytoarchitecture, as introduced by Brodmann to define a cortical map, serves as a hub, to which other data modalities can be related, to link together the different aspects of brain organization in an atlas.

[Parental care](#)

Definition

Any form of care that a parent devotes to their offspring at the benefit of the offspring fitness, which typically involves a cost to the parent, in terms of time and/or resource expenditure.

Introduction

Parental care includes any trait that has evolved in parents for the primary function of increasing the fitness of their offspring (Clutton-Brock 1991; Smiseth et al. 2012). Often, such traits are behavioral; parents exhibit behaviors which promote offspring survival, such as they build nests, forage to feed their young, and defend them against environmental hazards, from predators and parasites to adverse weather conditions.

For example, the female of the beewolf wasp *Philanthus triangulum* builds a subterranean nest in the sand and hunts for honeybees to feed her offspring. She flies around in places visited by foraging bees, identifies her target bee by smell and sight, and grasps and injects her target with venom. The bee will not die: she will be immotile – completely paralyzed – from now on. Then, the beewolf brings the bee to her nest – which is not a simple task, as the predator beewolf and the prey bee are approximately the same size. The nest is composed of a central tunnel and several side cells, one for each of the beewolf young. Typically, the beewolf places up to six paralyzed bee in a cell, lays an egg, and seals the cell – then she hunts for another bee, until all nest cells will contain the paralyzed bees and a beewolf egg (Strohm and Linsenmair 1999). In a few days, beewolf larvae will hatch from the eggs and they will feed on the paralyzed bees, until they will pupate and emerge as adult beewolves weeks later. In case parasite insects approach the nest (typically, parasitoids lay their eggs in beewolf nest, exploiting the preys stored by the beewolf for their own brood (Strohm et al. 2008)), the beewolf female attacks and kills them. This complex behavior – which includes building nests with a precise architecture, hunting for dangerous preys and moving them to the underground nest, defending the brood from parasites – has evolved because it favors the survival and development of the beewolf offspring.

Parental care may also comprise nonbehavioral traits, such as gestation and viviparity, where females take care of the early developmental phases of their young by keeping them into their body.

Parental care typically shows taxonomic patterns as for which sex cares (Reynolds et al. 2002) and whether it involves egg-attending, egg-caring, incubation, or provisioning the nest and/or feeding the young and protecting them from predators. Parents can care for their offspring temporarily, for short or long time periods during offspring development, or up to when offspring become adults. For example, females provide parental care in 90 % of mammalian families (and the remaining 10 % has bi-parental care), whereas most birds exhibit bi-parental care

(90 %) and only few of them have female-only care (8 %) or male-only care (2 %) (Gross 2005). In fishes, parental care is relatively rare, but, when it exists, it is more often provided by males. An important factor that contribute to set which sex cares for the young is whether egg fertilization is internal (i.e., it occurs in the female body) or external (i.e., it occurs in the external environment), which has consequences on parentage certainty (Royle et al. 2012).

Cooperative Care

In some species, other adults can cooperate with the parents in caring for the young. A typical example of cooperative care is that of meerkats, social mongooses inhabiting South African deserts. Meerkats live in groups and typically only one pair (the dominant female and male) reproduces. All other adult group members contribute to group living by taking turns in watching for predators while the other group members are foraging, and caring for the young, bringing them food, and defending them from predators, such as snakes (Clutton-Brock et al. 2001).

Parental care is also cooperative in some insects, e.g., social insects, where many (up to thousands) adults cooperate in caring for the brood of one or a few reproductives. In social insects the development of adult individuals may take from a few weeks to months during which the would-be-adults passes through different developmental phases (larvae hatch from eggs, they develop through several larval instars, then pupate, and will emerge later as adults) (Wilson 1971). During this time, brood develop in complex nests, which protect them from environmental hazards, and are fed one by one by workers who also protect them from enemies, such as parasites and predators.

Brood Parasites

Parental care is so costly that species exist that forego parental care by exploiting that of host species. The best known example is that of cuckoos,

Cuculus canorus. In this bird, females lay their eggs in the nests of another species, such as warblers, and the foster parents will incubate the cuckoo eggs and raise the cuckoo chicks, at the expenses of their own fitness. The cuckoo chicks evict the host eggs and kill the host chick, thus monopolizing all the host parents' care. Both cuckoos and their hosts have evolved special adaptations and counter-adaptations to limit parasite exploitation (on the host part) or to overcome anti-parasite defense by hosts (on the parasite counterpart). For example, cuckoos lay eggs which mimic those of the host in color and spot pattern and most hosts are able to detect (and eject) dissimilar eggs in their egg clutch (Davies et al. 1989; Kilner and Langmore 2011). Other animals have evolved similar parasitic behaviors, where the parasites do not exploit the host body, but simply one of its behavioral trait: parental care. For example, among social insects, social parasites exist who do not produce workers, as free-living social insects do, but exploit the nests and workers of host species to raise their brood, composed exclusively of reproductive males and females (Hölldobler and Wilson 1990).

Conclusion

Parentale care is a behavioural trait which offers many perspectives of conceptual and empirical analyses, in ontogenetic studies, genetics, ecology and in evolutionary biology.

Bruce J. Ellis

Tomás Cabeza de Baca
Health Psychology, University of California, San Francisco, San Francisco, CA, USA

Definition

Bruce Ellis is an evolutionary developmental psychologist who has made significant contributions to research on sexual development and reproductive strategies and on biological susceptibility to environmental stressors.

Introduction

Bruce Joel Ellis is an evolutionary developmental psychologist who has held academic positions at various institutions that include senior lecturer at the University of Canterbury and the John and Doris Norton Endowed Chair in Fathers, Parenting, and Families and professor at the University of Arizona. Dr. Ellis' most recent academic appointment is professor at the University of Utah in the Departments of Psychology and Anthropology. He is also the director of the Robert Wood Johnson Foundation Research Network on Adaptations to Childhood Stress. While Professor Ellis' contributions span across diverse domains of evolutionary psychology, his notable work broadly focuses on aspects of household and ecological context and its impact on sexual development and biological responses to stress. The following entry is divided by his private life, academic education, and his contributions to evolutionary psychology.

Private Life

Bruce Ellis was born on August 28, 1961, to Lois and Thomas Ellis and grew up in Berkeley, California. He is the lastborn of five siblings. Bruce is married to Kelly Hardesty and has two children, Leah and Joel Ellis.

Academic Education

Bruce spent the early portion of his academic training in California, studying at California Polytechnic, San Luis Obispo. At Cal Poly, Bruce discovered the field of evolutionary psychology and subsequently presented its basic foundations in his Sociology of Sex Roles class, challenging the professor's traditional perspective on gender and sex differences. The presentation was said to have "caused such a stir" that the professor spent 3 h in Gestalt therapy afterward (Ellis 2011, p. 158). In 1987, he received his Bachelor of Science degree in Social Science. Following his undergraduate work, Bruce began working with Donald Symons on research examining sex differences in mating behavior. Bruce's research, even early in his career, received attention from the media and in the scientific community. His initial first-authored publication (Ellis and Symons 1990) was featured in *Playboy* magazine (Ellis 2011) and became the most cited scientific paper ever written on sexual fantasy.

Bruce moved to the University of Michigan to work with David Buss, an evolutionary psychologist who specializes in individual differences and mate selection. Bruce was also mentored by Neil Malamuth, an evolutionary psychologist who applies tenets of natural and sexual selection to aspects of sexual aggression and coercion. The breadth of his graduate work focused on mating behavior, particularly emphasizing investment and dependence in sexual and romantic relationships. Bruce earned his PhD in evolutionary personality psychology in 1995.

Following his doctorate, Dr. Ellis became an NIMH T32 postdoctoral fellow in developmental psychopathology at Vanderbilt University

(1996–1999). He was mentored by Drs. Kenneth Dodge and Judy Garber, premier developmental researchers broadly focused on examining the ecological and biological factors that impact the development of aggressive behavior and mood disorders in children. Dr. Ellis' previous work primarily focused on individual differences in mating behavior but was agnostic to developmental processes that may influence the development of sexual and reproductive strategies. Dr. Ellis' early developmental work was largely influenced by the *psychosocial acceleration theory* put forth by Belsky et al. (1991). The developmental psychopathology fellowship and the psychosocial acceleration framework provided the foundations for Bruce to shift his research to adolescent and child populations and to integrate evolutionary reasoning with developmental processes. This continues to be his primary research trajectory.

Major Contributions to Evolutionary Psychology

Professor Ellis has been credited alongside Drs. David Bjorklund and Anthony Pellegrini for formalizing the field of *evolutionary developmental psychology*. As the name implies, evolutionary developmental psychology integrates evolutionary theory with developmental psychology to create a framework whereby the influence of phylogenetic and ontogenetic forces on social, cognitive, and physical development is simultaneously and interactively examined. Professor Ellis' work broadly focuses on how environmental and household conditions shape reproductive strategies (including pubertal timing, sexual debut, sexual risk behavior, and pregnancy) and individual trajectories and susceptibility environmental stressors. The brief review of Dr. Ellis' work will highlight his research on sexual development and reproductive strategies and biological susceptibility to environmental stressors.

Sexual Development and Reproductive Strategies The psychosocial acceleration framework put forth by Jay Belsky et al. (1991)

postulates that social and reproductive strategies in adolescence and adulthood are shaped by features present in early households, including socioeconomic status, parenting style, marital functioning, and parent-child relationship dynamics (Ellis and Essex 2007; Ellis and Garber 2000). One particular outcome that Dr. Ellis has focused on is pubertal timing in girls (reviewed in Ellis 2004). In 2005, Professor Ellis was a recipient of the George A. Miller Award for an Outstanding Recent Article on General Psychology for his comprehensive review of psychosocial and biological factors that impact the timing of puberty in girls (Ellis 2004). The review was additionally notable for integrating the disparate research findings from these two domains (psychosocial and biological) within a life history framework used by evolutionary developmental psychologists.

While most of the work cannot be covered in this entry, Dr. Ellis has consistently demonstrated that household quality (measured in many different ways) impacts reproductive strategies (assessed by varying self-report and biological measures). For instance, mothers with a history of depression and mood disorders had daughters with early pubertal timing (Ellis and Garber 2000). Results further demonstrated that this association was mediated by marital dysfunction and father absence, suggesting that the maternal mood disorder influenced the dynamics of the household by either causing (or a possible product of) the child's father to leave the residence (Ellis and Garber 2000). If he was still in the household, maternal mood disorder possibly caused marital discord between the parents. Ellis, along with his colleagues, was awarded another George Miller Award for creating theoretical distinctions for environmental and household stressors (Ellis et al. 2009). Traditional models of stress typically examine the effect of cumulative stress, the summation of acute and chronic stressors, and its effect on health and development. Ellis et al. (2009) created the distinctions between environmental harshness and environmental unpredictability as distinct stressors that, separately and in combination, produce distinctive developmental and health outcomes.

Biological Susceptibility to Environmental Stressors

The examination of environmental stressors and individual response to these stressors is another notable area of inquiry for Professor Ellis. Traditional stress models such as the diathesis-stress model put forth that the combination of genetic factors (diathesis) and environmental stress put certain individuals at increased risk for psychopathology. Evolutionary models of stress response, such as those put forth by Professors Ellis and Boyce (2005), provide an alternative to traditional stress models by reframing "vulnerability" to "susceptibility." In this model, certain individuals have endophenotypic susceptibilities that, in combination with environmental feedback, heighten or dampen the development of stress response systems. The rationale is that these individuals will best adapt to the environments they reside in. This stress response calibration has implications in life history domains. This *biological sensitivity to context* may be the neurobiological mechanism whereby household and environmental stressors outlined by the psychosocial acceleration model (Belsky et al. 1991) and examined by Bruce Ellis may facilitate in the development of social and reproductive strategies (Ellis 2004; Del Giudice et al. 2011). The biological sensitivity to context model has been extended and renamed as the Adaptive Calibration Model (ACM; Del Giudice et al. 2011; Ellis and Del Giudice 2014). The ACM states that the stress response system was designed to react to physical and psychosocial stressors present in the environment and to detect and encode features about the environment and inform development in ways that enhance the survival and reproduction of the organism. The ACM has been influential in guiding research on stress-health relationships.

Definition

The Centers for Disease Control and Prevention in the USA defines bullying as “any unwanted aggressive behavior(s) by another youth or group of youths” and involves a “perceived power imbalance and is repeated multiple times or is highly likely to be repeated” (Gladden et al. 2014, p. 7). Different researchers may define bullying differently, but they generally agree on three central characteristics for bullying: (a) intentionality, (b) repetition, and (c) an imbalance of power (Olweus 1993). Intentionality refers to the intent, desire, or aim to inflict harm (injury or discomfort) upon another person. Repetitiveness involves the frequency of the behavior. In general, bullying happens again and again, or the victims become afraid that it might happen again. The third criterion of a power imbalance is also important because it distinguishes bullying from other forms of conflict: power differences between the bully perpetrator and victim occur in domains that favor the perpetrator (e.g., in terms of social status or physical strength).

Introduction

Bullying is a prevalent problem among children and adolescents, with estimates suggesting that 17.9% to 30.9% of school-age children are

victimized at school in the USA (Rivara and Le Menestrel 2016). Involvement in bullying is related to concurrent psychological, social, and academic difficulties and long-term negative outcomes, such as problems in personal relationships, employment, mental health, and criminal offending (reviewed in Rivara and Le Menestrel 2016). These results, taken together, indicate the critical and urgent need for effective prevention and intervention programs to reduce bullying.

This chapter (a) highlights key theoretical perspectives on bullying, including social information process theory, social dominance theory, the social cognitive theory of moral agency, and the social-ecological framework; (b) discusses the impact of bullying on victims, bullies, bully-victims, and bystanders; (c) discusses factors related to bullying on the individual, familial, school, and cultural levels; and (d) briefly reviews components of effective bullying interventions and discusses promising bullying prevention and intervention programs.

Theoretical Perspectives on Bullying

Social Information Processing Theory

Researchers have studied bullying perpetration and factors that contribute to bullying for over three decades. Early theoretical perspectives on bullying are based on the research on aggression, conduct disorder, and emotion dysregulation. Early research in bullying considered bullies primarily as aggressive, antisocial agents with biases and deficiencies in their social information processing. Social information processing theory suggests that social information is processed in five stages: assessing and responding to social situations via social perception, interpretation of social cues perceived, goal selection, response strategy generation, and response decisions (Crick and Dodge 1994). Bullying behavior was understood to result from misinterpreting another's hostility (hostile attribution bias), showcasing biased social perceptions, and from reactive aggression to situations perceived as anger-provoking. As such, bully perpetrators were believed to have weak social skills that

cause them to engage in aggressive acts (Crick and Dodge 1994).

However, this understanding of bullies as primarily unskilled social participants was challenged after researchers distinguished between reactive and proactive aggression. Research demonstrated that bullying can also involve a *proactive, goal-directed* form of aggression rather than solely reactive aggression (i.e., intention-cue detection deficits that spur aggression). This distinction allowed the conversation to shift from bullies as solely socially unskilled or emotionally dysregulated children to bullies as *skillful manipulators* of social situations. Recent research suggests that some bullies are adept users of emotion understanding and theory of mind (which are aspects of social cognition) and that they use these skills to manipulate and organize others and achieve their social goals (Rivara and Le Menestrel 2016). Nonetheless, the occurrence of the “stereotypical bully” or “classic bully,” who is low on social skills and possesses few assets and competencies that the peer group values, is also supported by research (Olweus 1993). This heterogeneity in bully profiles likely stems from bullying being the result of a complex array of individual and environmental interactions.

Social Dominance Theory

According to social dominance theory (Pellegrini and Bartini 2001), bullying behavior can be adaptive, and individuals may use bullying and aggression as a means to gain high social status and access to more resources. This claim is supported by research that demonstrates that children who bully others often have social power within their peer network and can be perceived by peers as popular, socially skilled, and leaders (see Rivara and Le Menestrel 2016 for a discussion). Social dominance theory has been particularly useful in explaining the observed increase in aggression during the transition into middle schools. Bullying may increase during the transition to middle school because students tend to use aggression as a way to establish dominance within a group of new peers. School transitions mark a disruption of the dominance norms in the group,

as students who were the oldest and most powerful in elementary school invert to the youngest in middle schools. As these students “renegotiate their place in a large and more diverse peer group” (Pellegrini and Bartini 2001, p. 144), they renegotiate their dominance status using aggression. This increase in aggression may also be more dramatic among young adolescent boys, as they might be more likely to view aggression as socially acceptable and as an effective way to gain dominance and resources. After dominance is established at the end of sixth grade or seventh grade (about a year after school transition), aggression tends to decrease because students are aware of their status in relation to others, and the it may be too risky (e.g., the cost is too high) for individuals with lower status to challenge the individuals with higher status using bullying (Pellegrini and Bartini 2001).

The Social Cognitive Theory of Moral Agency

The social cognitive theory of moral agency suggests that moral behaviors develop as a product of their continuous and reciprocal interactions with both the social environment and internal stimuli, or cognitions (Bandura 1986). Moral reasoning is the process of reasoning between right and wrong in difficult situations. Self-regulation processes are required in order to exercise moral agency. Immoral behaviors, such as bullying or watching someone be victimized without intervening, are less likely to occur if the individual anticipates feelings of guilt and shame. However, individuals can use moral disengagement to avoid these negative feelings. Moral disengagement allows one to disengage moral standards to achieve absolution from guilt and to permit immoral conduct by using a series of cognitive processes (e.g., cognitive justification, minimizing one’s agentic role, disregarding or distorting the negative impact of harmful behavior, and blaming or dehumanizing the victim) (Bandura 1986). Research suggests that passive bystanders and bullies tend to feel less guilt or shame compared to children who often defend victims and moral disengagement has been found to predict aggressive and immoral actions, such as bullying (e.g., Wang et al. 2017).

Social-Ecological Framework

Researchers have suggested using a more comprehensive social-ecological framework to understand the complexity of bullying (Espelage and Swearer 2011; Swearer and Hymel 2015). This social-ecological model suggests that an individual interacts with his/her environment to shape outcomes. The environment includes factors and interactions among factors within the micro-, meso-, exo-, macro-, and chronosystems. In other words, individual level factors (such as social skills, empathy, emotion regulation, gender, age), family factors (e.g., parenting, domestic violence), school factors (school climate, student-teacher relationship), broader cultural factors (e.g., community violence, media), and time-related factors, as well as their interactions all contribute to involvement in bullying (Espelage and Swearer 2011).

As an extension of the social ecological framework, recently, researchers proposed integrating diathesis-stress model and social-ecological model (Social-Ecological Diathesis–Stress Model) to understand bullying and victimization. This theory suggests that the development of externalizing problems (e.g., bullying) may occur through interaction of one’s biological and cognitive vulnerability and stressful life events (e.g., maltreatment), and the complex interconnections among different systems in a child’s life that impact their outcomes. In other words, stressful life events can be exacerbated by biological diathesis (e.g., callous-unemotional traits, narcissism, and impulsivity) and cognitive diathesis (e.g., moral disengagement), which then lead to the onset and maintenance of externalizing problems, such as bullying (Swearer and Hymel 2015).

Impact of Bullying

Incidents of bullying involve multiple parties, including bullies/perpetrators, victims, bully-victims, and bystanders. Research has shown that the involvement of bullying negatively impacts everyone involved.

Victims

A vast amount of literature highlights the link between victimization and internalizing problems (e.g., depression, anxiety), low self-esteem, academic difficulties, as well as health concerns across different age groups (see review in Rivara and Le Menestrel 2016; Swearer and Hymel 2015). Although earlier research often used cross-sectional designs, recently several longitudinal studies have been used to provide a stronger link between victimization and later internalizing symptoms, such as depressive and anxious symptoms (e.g., Ttofi et al. 2011). Related to internalizing symptoms, some research supports that students involved in bullying are more at-risk for suicidal thoughts and attempts than their uninvolved peers. Victimization is also linked to later externalizing behaviors, especially for boys (Rivara and Le Menestrel 2016).

Bullies

In contrast to victimization, the consequences of perpetration have been less studied. Some research indicates that compared to their non-aggressive peers, perpetrators report lower levels of school engagement and belonging and higher rates of delinquent behavior outside school (e.g., Nansel et al. 2001). Research also suggests children who bully are more likely to exhibit psychosomatic problems when contrasted with their uninvolved peers (reviewed in Rivara and Le Menestrel 2016). Overall, more research that looks specifically at the consequences involved in bullying perpetration is still needed. This may include longitudinal research that tracks perpetrators' physical, psychosocial, and academic consequences over the short and long term.

Bully-Victims

Bully-victims likely represent the subset of bullies who are not socially adept or do not hold high social status. These students, who have the dual role of perpetrator in some situations and victim in others, tend to have worse outcomes than youth who are solely bullies or solely victims. Specifically, bully-victims report higher rates of depression, somatic complaints, and higher rates of substance use and suicidal ideation compared

to victims or bullies (see review in Rivara and Le Menestrel 2016). Research also indicates an increased probability for referral to psychiatric assessment compared to those who are primarily perpetrators and victims (Nansel et al. 2001).

Bystanders

Witnessing bullying behavior may also affect mental health. For those who have been victimized in other settings, observing the victimization of peers can constitute a psychological re-victimization or co-victimization, which can increase mental health risk (see Rivara and Le Menestrel 2016 for discussion). Even witnesses who have never been victims themselves may have heightened anxiety around their own vulnerability of being bullied, when witnessing a bullying event (Espelage and Swearer 2011). As such, it is likely that those who observe bullying are at risk for mental health concerns.

Factors Involved in Bullying

Gender

Gender differences in bullying and other violent behaviors are well documented. Overall, boys are more likely to report bullying perpetration compared to girls when it comes to physical bullying. However, gender differences in social aggression are less clear. In a recent meta-analysis, there were only slight differences (girls slightly higher than boys) in indirect/relational aggression across gender (Card et al. 2008). Differences in the rates of different types of bullying/aggression may arise from the effect of social stereotypes and prescribed gender norms: the idea that girls are more likely to spread rumors or engage in relational/social bullying can facilitate the actual occurrence of higher relational aggression in girls compared to boys. More research is needed to delineate how gender acts as a factor in different types of bullying perpetration.

Age/Grade Level

As suggested by the social dominance theory, bullying perpetration tends to increase at the end of elementary school to middle school years

and then decrease during the high school years (Olweus 1993; Rivara and Le Menestrel 2016). The increase in bullying after the initial transition to middle school suggests that students may use bullying as a way to gain social status with new peers after school transitions (see the social dominance theory section above for a discussion). Overall, older students are more likely to be a bully, less likely to be a victim, tend to exhibit lower rates of physical bullying, and show higher rates of relational bullying (Espelage and Swearer 2011). Sympathy for victims of bullying also decreases with the onset of adolescence. As such, some research indicates that younger children tend to be more supportive of victims, in terms of peer-reported defending behaviors (Salmivalli and Voeten 2004).

Disability

The prevalence of bullying among children and youth with disabilities varies across different studies, ranging from 10.7% to 94% depending on the sample and depending on the sample, disability type, educational placement (e.g., inclusion), and how bullying was defined (Rose et al. 2011). However, the overarching consensus in the literature is that disability status is a risk factor for involvement in bullying, both as perpetrators and as victims. Specifically, in bullying perpetration, individuals with certain behavioral characteristics, such as aggressiveness, challenging behaviors, and difficulties processing social cues, are more likely to bully others (Rose et al. 2011; Espelage and Swearer 2011). Students with disabilities who are placed in a restrictive or segregated educational environment (special education class) are more likely to engage in bullying. In addition, teachers' lack of intervention skills and awareness about different types of bullying are risk factors for student involvement in bullying. Furthermore, the severity and visibility of the disability, poor social skills, a lack of friendship or support network, and higher rates of peer rejection tend to increase the likelihood of victimization. These findings highlight the importance of providing individualized behavioral support to students with disabilities, such as social skills training, and of increasing teacher and staff

professional development to help detect and effectively intervene in reducing bullying. The current literature also points to the need for creating inclusive classrooms and educational environments where all students are supported and individual student needs are met (Rose et al. 2011; Espelage and Swearer 2011).

Social Skills

Social skills are observable behaviors that form an individual's overall social competence. Examples of social skills include empathy, assertiveness, cooperation, communication, engagement, and responsibility. Some bullies tend to lack basic social skills – and as such are both disliked by peers and viewed as unpopular (Olweus 1993). Other bullies hold considerable social power, are viewed as popular by their peers, and implement a sophisticated set of social skills that allow them to manipulate others (see Rivara and Le Menestrel 2016 for a review). Unlike some bullies and defenders, victims of bullying often lack social skills and struggle with peer interaction (Cook et al. 2010). As such, victims are often marginalized or disliked by peers and have fewer friends than those not involved in bullying. On the other hand, friendship can act as a protective factor against victimization; students who develop good friendships are less likely to be bullied and have fewer emotional problems (see Rivara and Le Menestrel 2016 for a discussion).

Empathy

Being able to understand and respond appropriately to others' emotions is crucial for developing healthy social relationships. In general, students who have higher levels of empathy are less likely to engage in bullying and more likely to engage in positive bystander behavior (i.e., defending the victim, supporting the victim, getting help from an adult) (Caravita et al. 2009). Importantly, research suggests there are different types of empathy, known as cognitive and affective empathy. Cognitive empathy refers to the skills and ability to recognize others' emotions and perspectives, whereas affective empathy refers to sharing others' feelings. When research differentiates between different types of empathy, different

patterns emerge. For example, Caravita et al. (2009) separated affective and cognitive empathy in their study and found that while affective empathy predicted defending behavior among boys in mid-childhood, cognitive empathy was positively related to bullying behavior in adolescence. These results indicate that the cognitive component of empathy does not necessarily impede aggressive behavior and instead may actually be leveraged by “ringleader bullies” who use their perspective taking abilities to maintain their social dominance. In contrast, affective empathy, or feeling what someone else feels, appears to be linked to defending behavior (Caravita et al. 2009).

Positive Psychological Traits and Bullying

Covitality is the emergence of positive mental health that results from possessing a personal arsenal of positive psychological assets. Recently, it has been used to evaluate the relationship between well-being and bullying. Covitality, amongst secondary aged students, is comprised of belief-in-self, belief-in-others, emotional competence, and engaged living. Studies have shown that even negligible amounts of victimization are detrimental to belief-in-others, belief-in-self, and engaged living (Lenzi et al. 2015). This demonstrates that victimization, in any amount, is harmful to subjective well-being. Further, in general, the more assets youth have, the less likely they are to experience physical or relational victimization. Taken together, research suggests that positive psychological traits are associated with bullying victimization and perpetration across grade levels.

Emotional Regulation

Emotional regulation plays a key role in students' social relationships. Students with poor emotional regulation skills may respond to bullying in aggressive or emotionally charged ways, increasing the likelihood they will be victimized in the future (reviewed in Rivara and Le Menestrel 2016). Interventions that target crucial emotional regulation skills could help victims improve their response to bullying to lessen the likelihood of the bullying continuing and also reduce the impulsivity that may be associated with bullying

perpetration in aggressive students. In addition, teaching students problem-solving skills to negotiate peer conflict may prevent them from engaging in bullying and victimization (Cook et al. 2010).

Internalizing Symptoms

While most longitudinal studies assert that psychological problems *result* from being bullied (e.g., Ttofi et al. 2011), other studies have found a “symptom-driven pathway,” where internalizing symptoms predict greater self-reported peer victimization (e.g., Kochel et al. 2012). Youth who struggle with depression have a negative cognitive style and frequently also struggle with interpersonal relationships or display a behavioral style that is perceived poorly by the peer group (Kochel et al. 2012), increasing the risk that they will be victimized. Overall, it appears that internalizing problems can function as both antecedents and consequences of bullying.

Family Factors

Punitive/harsh parenting, a high level of family conflict, and a lack of parental warmth and involvement are risk factors for bullying involvement (see Espelage and Swearer 2011 for discussion). Authoritarian parenting – a style associated with parents who are highly demanding, punitive, and less emotionally responsive to their children – is associated with aggressive behavior and bullying. Bullies tend to describe their families as having high levels of negative affect and conflict and describe their parents as indifferent and uninvolved (Espelage and Swearer 2011). It is possible that parents may model aggression during family conflict, and youth might imitate parents' behavior and using bullying to solve peer conflict. In addition, when parents are uninvolved and do not provide necessary supervision and monitoring, adolescents are more likely to be involved with deviant peers, which contributes to problem behaviors, such as bullying.

Unlike the families of bullies and bully-victims, which exhibit low cohesion and high conflict, families of victims are frequently enmeshed, with parents who are overprotective (Lereya et al. 2013). Additionally, child maltreatment is a risk

factor for victimization; children who have been abused or neglected by parents are significantly more likely to be a bully-victim or victim (Lereya et al. 2013).

Peer and School Factors

Research has repeatedly shown that school climate plays an important role in students' involvement in bullying. When students experience a negative climate at school, their bond to the school may be broken, leading them to be less likely to follow rules, including those regarding bullying. In addition, when students perceive bullying behavior as normal and approved by peers and teachers, their belief that school can effectively supervise or control their behavior is diminished; as a result, they are more likely to engage in bullying behavior and less likely to offer assistance to the victims during bullying incidents. A few important components in school climate that are related to bullying include positive student-teacher relationships, peer support, clear expectations, and consequences (for problem behavior) at school, and respect for diversity (Wang et al. 2013).

Student beliefs and attitudes surrounding aggression are another crucial element of school climate. Attitudes and peer norms regarding bullying are significantly related to bullying behavior of children (Duffy and Nesdale 2009). Although classroom norms influence children's behavior, pro-bullying peer group norms may override anti-bullying classroom norms and lead to an increase in bullying behavior in peer groups where bullying is accepted (Duffy and Nesdale 2009). As such, the "popularity norm," or whether popular students successfully use bullying as a means to establish social status, is a better predictor of bullying behavior in late elementary school than classroom norms (Dijkstra et al. 2008). When peers accept or reinforce bullying behavior by giving the perpetrators higher social status, bullying is likely to continue. A study examining the impact of bystander behavior on bullying found that bullying was negatively associated with prosocial bystander behavior (e.g., students defending the victim) and was positively related to reinforcing bullying behavior (Salmivalli et al. 2011). This finding supports the contention

that bullying is not an isolated event between a bully and a victim, but rather is a group phenomenon (Salmivalli et al. 2011). As such, school-level factors, such as school climate and peer norms, play a crucial role in impacting bullying behaviors.

Broader Social and Cultural Factors

In addition to individual, family, and school-level protective and risk factors, there are several broader social/cultural factors that contribute to bullying. For example, cultural values such as individualism have been linked to aggressive behavior. Exposure to violence in the community (e.g., living in an unsafe neighborhood, gang affiliation) or through media (e.g., TV, video games), and poverty has also been linked to aggression/bullying (Espelage and Swearer 2011; Swearer and Hymel 2015). However, the causal relationship between bullying and those social-cultural factors remain unclear.

Intervention Programs for Bullying

Effectiveness of School-Based Prevention and Intervention Programs

During the past two decades, an increased number of prevention and intervention programs targeting bullying have been developed. However, there is mixed evidence for how effective school-based programs are in preventing bullying in the USA. Some meta-analytic studies of bullying interventions have shown limited or even negative effects for decreasing bullying at schools (see Nickerson 2017 for a review). Other meta-analyses on bullying preventions/interventions suggest more positive and robust outcomes for students, such as increasing students' positive attitudes toward their school, reducing rates of bullying, and increasing positive bystander behaviors (Farrington and Ttofi 2009; Yeager et al. 2015). Researchers have posited that bullying program effectiveness appears to differ depending on methodology and experimental design, setting, developmental level, outcomes, and by specific program components (Nickerson 2017). The rest of this section visits each of these considerations in further detail.

Methodology and Experimental Design

The mixed findings that surround the effectiveness of bullying interventions may partly stem from the use of different inclusion criteria across studies (e.g., language, type of publication, sample size, types of bullying outcome measures, and a focus on studies conducted in North America) (Bradshaw 2015). The effectiveness of intervention studies is also impacted by challenges with experimental design: studies often lack a control group to examine causal effects, they sometimes lack the long-term follow-up studies which are needed to demonstrate that the intervention has lasting effects, and they rarely use randomized controlled effectiveness trials. The benefits of effectiveness trials are that an intervention is carried out by school personnel (e.g., teachers instead of trained researchers) to test the effectiveness of the intervention in more naturalistic settings (Bradshaw 2015). Yet research frequently only involves efficacy studies that inflate intervention success, as interventions tend to be implemented by highly trained researchers in controlled settings with optimal conditions. Due to the current gap between research and practice in psychology, more research is needed to examine the effectiveness of bullying prevention programs carried out by nonresearchers in real world environments.

Setting

The setting or location of an intervention also impacts its effectiveness. A comprehensive meta-analysis by Farrington and Ttofi (2009) found that bullying and victimization outcomes were less effective in the USA and Canada when compared to European countries. These results were replicated in a systematic review of bullying research, which found that the majority of studies that observed significant effects on bullying behavior appeared to have been conducted outside of the United States and with relatively homogenous samples (Evans et al. 2014). Researchers posit that North America may be a particularly difficult setting in which to design and deliver bullying prevention programs due to the heterogeneity of the intervention population (e.g., diversity of race/ethnicity, socioeconomic status, and income

inequality). Interventions in North America may require more culturally sensitive and targeted bullying interventions (Evans et al. 2014). As such, more research is warranted to determine how characteristics of the setting of bullying interventions may impact program effectiveness.

Developmental Level and Outcomes

The effectiveness of bullying prevention programs also likely depends on the developmental level of students. While most research supports that bullying interventions have a stronger effect on decreasing bullying perpetration in middle school age and older students than on younger students (Farrington and Ttofi 2009), recent meta-analyses have suggested the opposite. Yeager et al. (2015) found some effectiveness for bullying prevention programs in grades 7 and below, nullified results in grade 8, and harmful effects of bullying prevention programs in grades 9–12. As such, more research is warranted to determine how different outcomes across different age groups are impacted by bullying prevention and intervention.

Program Components

Specific program components also impact the effectiveness of bullying prevention and intervention programs. The literature considers components for decreasing bullying and victimization to include (a) developing a caring school climate by fostering empathy and kindness among students; (b) promoting students' and staff's awareness and knowledge of bullying; (c) using consistent language to enforce school-wide rules and consequences for bullying; (d) increasing adult supervision of all students on the playground; (e) providing training to promote skills and competencies for students (e.g., conflict resolution, self-regulation, problem solving) and teachers (e.g., how to handle bullying behavior, classroom management, establishing classroom rules); (f) increasing adults' role modeling of appropriate and prosocial behavior; (g) encouraging bystanders to intervene in bullying situations; and (h) involving parents (parent trainings, meetings) (Farrington and Ttofi 2009; Bradshaw 2015).

Review of Effective Bullying Intervention and Prevention Programs

Bullying interventions can successfully integrate key components (as discussed above) into a cohesive bullying prevention/intervention by considering a multitiered approach that addresses the specific social environment and educational context of the bullying phenomena. This includes systems-wide awareness, training, and discussions involving all students and stakeholders (teachers, parents, and staff) in conjunction with more targeted interventions at the peer-group and individual level for students that need additional intervention. Research supports that this multitiered, comprehensive approach is a promising way to reduce bullying perpetration (Farrington and Ttofi 2009; Bradshaw 2015). Several multi-level interventions (or interventions that can be adapted into a tiered approach) and that demonstrate promising results for bullying prevention outcomes are briefly summarized below.

Olweus Bullying Prevention Program

The Olweus Bullying Prevention Program pioneered the whole-school approach to preventing and reducing bullying (Olweus et al. 1999). This large-scale intervention, designed for all grade levels, includes school-wide components (e.g., coordinating committees, anti-bullying school rules, events, playground supervision), classroom-targeted components (classroom meetings and activities, videotaped classroom curriculum), and bully- and victim-targeted components (e.g., talking with the perpetrator, providing consequences, supporting the victim). Additionally, partnerships between parents and the school are encouraged. Results of the Olweus Bullying Program indicate general success in decreasing bullying, victimization, and antisocial behavior and in improving school climate (Olweus et al. 1999). Furthermore, in a comprehensive review, programs based conceptually on the Olweus Program were found to be more effective than their counterparts, although these effects were more consistent in non-US countries. Importantly, the strongest effects were found in studies that had a less rigorous experimental design (namely age-cohort designs) as opposed to a more rigorous

experimental design (randomized controlled trials) (Farrington and Ttofi 2009).

KiVa

The Finnish KiVa program (an acronym for *Kiusaamista Vastaan*, “against bullying”) is a bystander-based whole-school approach that attempts to reduce the social rewards and motivation of bullies by targeting bystander reactions and behaviors toward bullying events. The program targets bystander empathy, self-efficacy, antibullying attitudes, and bullying prevention skills via classroom lessons, activities, and rules, videos, and computer games. Posters and recess supervisors in vests also serve as a visual reminder to students and school personnel about the program. Parent guides on bullying and prevention are also distributed. Cases of bullying are addressed by a small team of teachers who facilitate individual and small-group discussions with the victims and bullies. Additionally, the classroom teacher meets with two to four prosocial and high-status classmates, encouraging them to support victims. Results of this intervention suggested reductions in bullying (grades 1 to 6) and victimization (grades 4–6), increased self-efficacy for defending and bystander assistance (grades 4–6), and decreased bullying reinforcement (grades 4–6 and grades 7–9) when compared to control groups (Kärnä et al. 2013).

Bullying Prevention in Positive Behavioral and Intervention Supports

Recent researchers have suggested following the Positive Behavior Supports (PBS) framework for bullying prevention. The Bullying Prevention in Positive Behavior and Intervention Supports (BP-PBIS) is a school-wide system for facilitating positive behaviors among both staff and students. Under the BP-PBIS model, school personnel can readily integrate key factors of bullying intervention across primary (school-wide), secondary (classroom or group level), and tertiary (individual) systems of support to improve school safety and prevent bullying behavior by making bullying behaviors less effective and relevant and making prosocial behavior more rewarding (Sugai et al. 2011). Facets of BP-PBS included

creating and following school-wide rules surrounding bullying, teaching students social responsibility skills, explicit instruction to students on what constitutes gossip, inappropriate remarks, cyber bullying, supervising student behavior, and faculty follow-up. BP-PBIS studies document a decrease in school suspensions and office discipline referrals for bullying behavior (e.g., see Nickerson 2017 for a review).

Social Emotional Learning Programs

Social Emotional Learning (SEL) programs explicitly teach social skills (e.g. empathy, relationship building, coping, prosocial behaviors, decision-making) as a way to improve academic and social functioning in schools. Although SEL programs rarely target only bullying behaviors, most SEL programs that aim to promote a positive school climate and decrease violent and disruptive behaviors also successfully decrease bullying and victimization (see Bradshaw 2015 for further discussion). For example, in a large-scale randomized controlled trial, using an SEL program (The Second Step Program), middle school students with disabilities experienced reduced bullying (see Nickerson 2017 for a review). SEL programs are often Tier 1 or universal programs (social skills lessons delivered to an entire school) and few programs utilize a multitiered framework in order to provide more intensive interventions for students in need. However, research suggests intensive social skills training can also be helpful for small groups of youth at risk for becoming involved in bullying or aggression (e.g., Coping Power Program). As such, future research may investigate including more intensive social skills training and emotion regulation approaches to supplement universal SEL approaches (see Bradshaw 2015 for further discussion).

Conclusion

Bullying is a very complex phenomenon, and involvement in bullying negatively impacts everyone involved, including bullies, victims, bully-victims, and bystanders. Factors at different

levels (microsystem, mesosystem, exosystem, macrosystem, and chronosystem) and their complex interactions all contribute to the development and maintenance of bullying behavior. Although there is some evidence for the effectiveness of bullying prevention and intervention programs, more rigorous research is needed. Only when all factors contributing to bullying are taken into consideration in designing and implementing the prevention and intervention programs, will schools be free from bullying.

Definition

Established burial rites, ceremonies, and customs performed publically and/or privately by individuals or groups in the disposition of human bodies as prescribed by religions and cultural customs.

Introduction

Human remains indicating ritual disposition have been discovered throughout Europe and Asia dating back more than 100,000 years. Human burial rituals have long been considered within the social science community as universal expressions that affect and promote in-group cohesion and serve various cultural and religious functions. Evidence of ritual burials includes the specific arrangements of human remains with primitive tools, foods, weapons, and animal bones buried on or near the bodies. There has been increasing agreement among psychologists and anthropologists that traditional rituals such as human burials are considered as early evidence of human social cohesion and are believed to help establish and maintain group identity. Burial rituals emphasize communities' commonly shared life and death experiences, indicating human contemplations of the origins of creation and the veneration of ancestors. Religious scholars and social scientists agree that burial rituals are significant features of most world religions, influencing the cohesion of the cultural groups that practice them, providing practical benefits for individuals, and informing the practitioners' beliefs about life after death (Durkheim 1912/2008).

Earliest Evidence of Ritual Burials

The first hominids believed to ritually bury their dead were Neanderthals, our closest extinct human relative. *Homo neanderthalensis* lived in Europe and southwestern to central Asia between 400,000 and 40,000 years ago (Edgar and Johanson 2006). Most anthropologists and scholars agree that at least some Neanderthals ritually treated and buried their dead (Pettitt 2002). Neanderthals, who archeologists have determined lived as contemporaries with *Homo sapiens* for hundreds of thousands of years, are believed to have ritually disposed of bodies. Evidence of their burial practices, which include placement of corpses in shallow graves along with common stone tools and animal bones, are believed to indicate an emotional connection with the deceased. Dozens of their gravesites have been discovered throughout the Middle East and Europe. The oldest confirmed burial took place at Tabun Cave in Israel, around 100,000 years ago wherein the remains of a Neanderthal woman were discovered, seemingly positioned with the woman partially placed on her left side near the edge of the cave (Drake 2015).

At another site in the hills north of Madrid, Spain, archeologists discovered what is thought to be firm evidence of Neanderthals funereal rituals wherein the jaw and six teeth of a Neanderthal toddler were found amidst the remains of a series of charred hearths. There, scientists discovered several dozen herbivore antlers and a rhino skull that appeared to have been purposefully arranged in a burial ritual between 38,000 and 42,000 years ago. The inclusion of fauna, flint tools, and other artifacts in the burial sites points to Neanderthal beliefs in the spirit world and an afterlife.

Modern Human Burials

The earliest known burial site of modern humans was discovered in 1933 in a cave in Oafzeh, Israel. It contains 100,000 year old skeletons of children and adults stained and intentionally buried with lumps of red ochre. Ocher is a natural pigment

containing iron oxide, which varies in color from red to brown to yellow. The Oafzeh site also included the mandible of a wild boar and the antlers of a red deer. The remains of as many as 15 individuals were found along with dozens of fragments of red ochre and ochre-stained stone tools assembled near the human bones, leading most scientists to concur that the ochre was used in a death and burial ritual. The presence of ochre lumps led some archeologists to believe that the individuals who conducted these burials possessed some level of developed language and mathematical abilities representing symbolic thought. Evidence of such early human ritual burial behavior is also thought to represent an awareness of the conditions of life and death. These burials included evidence of artifacts seen as representations of religious rituals indicating possible concern for the dead in the afterlife (Lieberman 1991). Corpses were often buried with remnants of stone tools and parts of animals and positioned with deliberate care in holes in the ground. They often appeared as having been specially protected from the environment and animals, with some scientists positing that the dead seemed to have been lovingly cared for, which could indicate a faith in the afterlife.

Ritual Burials and Religion

The earliest evidence in the archeological record suggesting a belief in the afterlife evidenced by ritual burials coincided with the appearance of modern humans, during the “cultural big bang” 40,000–60,000 years ago (Mithen 2004). From the perspective of most of the world’s religions, ritual disposal of human dead serves to bring closure for the surviving family and friends of the deceased and shows respect for the departed. Burial rituals are also believed to assist the departed in their transition to the next life. Early human behavior as demonstrated in ritual burials is thought to represent cognition of the differing stages of life and death. For example, human remains found in Turkey revealed evidence of funerary practices 8,000 years ago in that the

bodies were elaborately manipulated before burial (Whitehouse 2012). The placement of corpses in shallow graves along with common stone tools, food items, weapons, and animal bones indicate an emotional connection to the deceased and reveal efforts by the living to support the deceased in an afterlife. These types of ritual burials are believed to have served a number of different goals, including honoring the dead and communing with gods and spirits as well as supporting bonding in-group activities (Whitehouse 2012). Regarding the continued development of religious beliefs in mortuary practices, it is likely that funeral rituals expanded over time, becoming more delineated and increasingly complex as the various religious beliefs in the afterlife became systematized and codified.

Burial rites often appear to correspond to three essential life transitions on a continuum of life to death and post-death experiences for the dying individual, the attendant(s) providing the ceremony, and the friends, family, and in-group members who witnessed their transition (Gennup [1960] 2004). According to Gennup, the life to death transition can be considered as a three-step process beginning with the preparation of the dying person, including the giving of the last rite(s), followed by the rites of transition which include the final burial of the corpse in a designated place, ending with rites of incorporation such as a prayer service offered with the intention of praying for the salvation of the deceased person’s soul (Gennup [1960] 2004). Human birth, marriage, and death express common and critical biological and social changes, making ritualized acknowledgments increasingly vital for individuals and groups. As in the performance of other religious rituals, there seems to be a tendency during burial rites wherein the community members conducting the rituals summon or invite the god(s) and spirits to assist the living. It is as if the mystery of physical death and the yearning for the assurance of an afterlife are issues which the living cannot understand or attend to without supernatural assistance, and only when the living adherents offer obeisance to their god-figures can there be an expectation of the burial rituals succeeding.

Among competing theories regarding the importance of burial rites is the idea that ritualized burials serve to restore the belief in society's permanence which is challenged whenever individual members die (Hertz 1960). Funereal rituals provide opportunities for those surviving members of the clan or culture to find common belief, faith, and to perform accepted life to death rituals which have the intention and result of affirming a genuine solidarity of purpose and unity for the group (Hertz 1960).

Ritual Burials and the Distinction Between Neanderthals and Modern Humans

It is widely accepted that Neanderthals disappeared approximately 35,000 years ago. While it has been common practice for many researchers to differentiate Neanderthals from modern humans based on their capacity for symbolic behavior as evidenced in ritual burials, recent discoveries and studies are leading some scientists to challenge the notion that early modern humans' ritualized burials were more sophisticated than Neanderthals (Riel-Salvatore and Gravel-Miguel 2013). Burial rituals have long been thought of as expressions of abstract thinking, but archeologists and social scientists are discovering evidence of Neanderthal practices commensurate with those attributed to modern humans (Riel-Salvatore and Gravel-Miguel 2013). The complexity and variety of ritual burials appear to indicate that human behavior does not always present as having evolved from simple to complex and is subject to variant living conditions and geographical locations at the times of the burials.

Conclusion

Throughout early and modern human history, burial rituals have been used to promote in-group functionality and bonding by establishing and maintaining group identity and norms. Ritual burials appear to have served to

provide opportunities for families and group members to honor their deceased for their contributions to the group and to prepare the dead for their journeys in the afterlife. Archeological evidence of tools, weapons, and food found buried with human remains support the theories that Neanderthals and early modern humans ritualized life to death transitions. Scientists continue to study how ritual burials evolved to address the universal human experiences of life and death, and beyond.

Butterfly Mimicry

Karin Kjærsmo

Synonyms

[Protective resemblance](#)

Definition

Protective resemblance between a butterfly and two or more species, or between a butterfly and an inanimate object.

Introduction

Butterfly mimicry is a form of protective coloration where a given species, commonly referred to as the *mimic*, increases its chance of survival by visually resembling a harmful species, the *model*, such that the receiver of the signal, the predator (e.g., birds, reptiles, or predatory insects who attack and consume butterflies), gets confused between the two and avoids the mimic (Ruxton et al. 2004). The model can either be a different species of butterfly or an entirely different species of animal. In its broadest sense, butterfly mimicry may also involve a third category, a camouflage strategy known as *Masquerade*, in which

butterflies mimic inanimate objects such as leaves, bits of lichen, or patches of tree bark (Ruxton et al. 2004). Traditionally, however, there are two main types of mimicry, and these are typically distinguished from each other by whether the mimic's signal involves deception of the predator or not (Turner 1984). In *Müllerian mimicry*, named after the German naturalist Johannes Friedrich "Fritz" Müller, who first proposed an evolutionary explanation for the phenomenon, both the mimic and the model species are harmful to the predator, which is why the signal is considered to be honest in both species and does not involve deception of the predator. Dishonest signaling through the mimicry of a harmful species by a harmless species, on the other hand, does involve deception of the predator and is known as *Batesian mimicry*, named after the English naturalist Henry Walter Bates (Bates 1862).

Müllerian Mimicry

In Müllerian mimicry, both the mimic and the model species also have, in addition to warning signaling coloration effective secondary defenses. These defenses can be either morphological, such as spines, or chemical, such as toxins. Both species benefit, because a potential predator has more opportunities to learn the meaning of the signal, which is why the relationship between Müllerian mimic and model species is said to be *mutualistic* (beneficial to both organisms). The signal receiver (predator) also benefits from this system, as it avoids potentially harmful encounters. In 1879, Müller, who at the time studied Neotropical butterflies in Brazil, published a simple explanation for this phenomenon stating that "defended species may evolve a similar appearance so as to share the costs of predator education" (Müller 1879; Ruxton et al. 2004). Müller was also the first to mathematically describe a survival benefit of being a Müllerian mimic depending on the abundance of similar and dissimilar species in its environment. The mathematical model has recently been extended to include unequal levels of unprofitability of the species to predict the relative benefit (Mallet 2001). Two types of experimental evidence for Müller's suggested

predatory mechanism underlying Müllerian mimicry have been put forward. The first is that rare unpalatable forms tend to have lower survival rates when they are distinct in appearance compared to when they are more similar to a common unpalatable species (Benson 1972). The second is that naïve predators tend to typically take a few of each unpalatable form before they start to avoid them (Kapan 2001).

Several examples of Müllerian mimicry are found among the distasteful Neotropical butterflies of the subfamily *Heliconiinae* (“longwings”) in South America (Ruxton et al. 2004; Mallet and Gilbert 1995). Many longwings form assemblages of similarly looking mimic and model butterflies known as *mimicry rings* or mimicry complexes. At least four distinct assemblages including butterflies from the *Heliconiinae* and other species are traditionally recognized, the *tiger*, *red*, *blue*, and *orange* ring (or complex) (Mallet and Gilbert 1995). The *tiger* ring consists of about 200 Neotropical species which all share a similar pattern of orange and yellow stripes on a black ground color. The *orange* ring is comprised of a group of bright orange species (including, e.g., *Marpesia petreus*, *Dryas iulia*, and *Eueides aliphera*). Additionally, there are several species pairs, the most well known of which is the *red postman* butterfly (*Heliconius erato*) and the *common postman* (*Heliconius melpomene*). Another classic example of Müllerian mimicry is the monarch butterfly (*Danaus plexippus*), which forms a Müllerian complex together with the viceroy butterfly (*Limnitis archippus*). This example was long believed to be a case of *Batesian mimicry*, with the viceroy mimicking the monarch, but research has shown that both species are harmful to predators as they both contain toxins (arguably even more so in the viceroy than the monarch), hence they are Müllerian mimics (Ritland and Bower 1991). In addition to sharing similar coloration patterns, members of each mimicry complex also tend to display similar behaviors. For example, many butterflies of the same mimicry ring form communal roosts at night, a behavior that has been shown to deter predation by birds as it increases the strength of their warning signal (Finkbeiner et al. 2012). Butterflies of each ring

also tend to fly together at day, occur in similar habitats and at similar heights above the ground, and also get together at the same time of year (Mallet and Gilbert 1995).

Evolution of Müllerian Mimicry

The more than century-old question of how Müllerian mimicry evolves is not yet fully understood. Broadly speaking, mimicry can evolve either via *advergent* or *convergent* evolution. In *advergent* evolution, the model species would remain the same, while selection acts on the mimetic species, bringing about a resemblance to the model species. In *convergent* evolution, a common selective pressure would act on all species involved, bringing about an overall resemblance between them. *Advergent* evolution via the so-called *two-step hypothesis* is the most widely accepted model for the evolution of both Müllerian and Batesian mimicry (Ruxton et al. 2004). The *two-step hypothesis* entails that mimicry evolves in two stages, the first stage is a mutational leap of the mimic toward the model which establishes an approximate similarity. This stage is then followed by gradual evolutionary change which fine-tunes the mimic’s similarity to the model (Turner 1984). One of the most frequently asked questions related to the evolution of Müllerian mimicry is: How do we know which one is the model and which one is the mimic? If Müllerian mimicry evolves through *advergent* rather than *convergent* evolution, scientists have argued that the *models* are expected to be: (1) more unpalatable, (2) more common, (3) earlier (in seasonal species), (4) larger, (5) more conspicuous, (6) more gregarious, and should have (7) a wider geographic distribution, (8) less “fuzzy” color patterns, (9) more ancient color patterns, (10) less polymorphism, and (11) less overall divergence from an ancestral color pattern than their *mimics* (Mallet 2001).

Batesian Mimicry

In *Batesian* mimicry, the mimic itself lacks an effective secondary defense, and so it is harmless to the predator, but the mimic still gains protection from predators by resembling a harmful model. As opposed to the mutualistic relationship

between Müllerian mimics, Batesian mimicry is considered to be *parasitic* (beneficial to the mimic while harmful to the model). Predators that attack the harmless mimics would soon learn that such organisms are profitable to attack and consequently, an increased number of Batesian mimics would lead to a decrease of the efficiency of the model's warning signal and so the survival of both model and mimic is reduced. Thus, the efficiency of Batesian mimicry is highly dependent on the abundances of the models and mimics and is normally considered to be effective when the unpalatable species are more abundant than the palatable species. However, the efficiency of Batesian mimicry is also dependent on the level of harm caused by models and the abundance of alternative prey (Ruxton et al. 2004). The most fundamental empirical evidence to support Batesian mimicry is that predators that have prior experience with unpalatable model species subsequently also avoid harmless species that resemble them.

Some examples of Batesian mimicry in butterflies can be found between species of the Neotropical, palatable *mimic sulfurs* (subfamily *Dismorphiinae*) and unpalatable *Ithomiini* butterflies which belongs to the *milkweed butterflies* (subfamily *Danainae*). The palatable spicebush swallowtail (*Papilio troilus*) is considered a Batesian mimic of the unpalatable pipe-vine swallowtail (*Battus philenor*). Some hawkmoth caterpillars (family *Sphingidae*), and pupa (e.g., *Dynastor darius*) have been suggested to be Batesian mimics of snakes (Ruxton et al. 2004), although this resemblance has not been tested with nonhuman predators. In cases where caterpillars and pupa resemble snakes, the resemblance between mimics and models cannot be explained by shared ancestry; however, in some cases of resemblances between adult butterflies, it is likely that the resemblance between species can be explained by shared ancestry.

Conclusion

Many mimetic systems involve a complex interplay of species which vary in their defensive attributes and predators which vary in their abilities to

deal with them. Even in Müllerian mimicry, prey may be unequally unpalatable and edibility may not be an absolute condition (Speed 1999). Different predator species may have different degrees of tolerance and an individual predator's motivation to attack prey might vary with its nutritional state, meaning that predators may still feed on weakly unpalatable prey when hungry or when there is a lack of alternative prey. In such cases, the mimetic relations between unequally defended species could be parasitic, and this phenomenon has been referred to as quasi-Batesian mimicry. As there exists a whole range in between Müllerian and Batesian mimicry, it may not always be appropriate nor simple to divide mimetic species between these two categories.

By-Product

Christopher S. Tripoli¹ and Michal Fux²

¹American University, Washington, DC, USA

²Northeastern University, Boston, MA, USA

Synonyms

Epiphenomenon; Side effect; Spandrel

Definition

A characteristic that arises incidentally alongside proper adaptations, rather than having been directly selected for in its own right.

Introduction

Evolution produces three types of phenotypic features: adaptations, noise, and by-products (e.g., Gould and Lewontin 1979; Buss et al. 1998). *Adaptations* are features directly selected for because of their beneficial effects on an organism's fitness. *Noise* refers to the products of random, neutral mutations and other chaotic processes such as genetic drift. *By-products*, which do not necessarily benefit reproductive fitness, are characteristics emergent of more fundamental adaptations; thus, they are "unintended" in an evolutionary sense.

Buss et al. (1998) distinguish between functionless by-products, exaptations, and co-opted spandrels. They describe functionless by-products as features that provide no evolutionary benefit to their carriers and are simply emergent derivatives of certain adaptations. Exaptations are preestablished adaptations that come to serve new evolutionary purposes over time, perhaps in response to changing environmental needs. Finally, co-opted spandrels originally emerge as functionless by-products but later become "co-opted" for new survival or reproductive purposes.

What follows is a description of the "clues" that can indicate a feature is a by-product rather

than an adaptation, including notable examples from the literature and an overview of current debates regarding the concept's application.

Identifying By-Products

Compared to adaptations, by-products may appear rudimentary or vestigial (Puts and Dawood 2006) or fail to embody "special design" principles of evolvability, reliability, efficiency, economy, precision, functionality, and complexity (Buss et al. 1998).

According to the principle of *evolvability*, the ability to drive a car cannot be a cognitive adaptation, as cars were not a feature of the early human environment and selection is not rapid enough to have produced functional driving adaptations over the last couple of centuries. Thus, the logical conclusion is that driving simply recruits a number of adjacent mechanisms such as motion tracking, spatial thinking, and motor functioning. Similarly, humans could not have evolved specific mechanisms for understanding social nuance in text messages; instead, they must draw on "stone-aged" social architecture, often causing interpretational issues and social anxiety (Srivastava 2005) (also see "Mismatch Hypothesis").

The *complexity* criterion asserts that any highly developed, cognitively "impressive" trait is likely to be an adaptation; for instance, the ability to infer the emotional states of others (e.g., Brüne and Brüne-Cohrs 2006) necessitates complex mental representations characteristic of theory of mind (ToM) ability.

The idea of "mental math" adaptations might simultaneously violate the principles of *reliability*, *efficiency*, *economy*, *precision*, and *functionality*. There appears to be unprecedented variability in mathematical ability, and many individuals struggle to acquire mental math skills despite steady entrainment in school settings. Additionally, people draw upon numerous linguistic, heuristic, and perhaps visuospatial resources from working memory when performing mathematical computations, hindering efficiency and accuracy.

Tooby (1999) argues that the deductive scientific procedure for determining by-products

from adaptations is of the same kind used in any other investigation; consider the observed mechanistic underpinnings within the “space of possibilities” to evaluate whether they perform better than a null stochastic account would predict. This sort of analysis, argues Tooby, could be performed at the genomic level, for instance, by comparing randomly generated nucleotide sequences to actual ones and employing traditional significance-testing procedures. Tooby also suggests applying the same logic to “adaptations involving larger anatomical structures, physiological processes, enzymatic pathways, the physical distribution of proteins in tissues, the timing of events in development, the logical organization of computational circuitry, or the patterns in behavior.”

Another pertinent methodological concept is that of “double-dissociation” (e.g., Hillis and Caramazza 1991; Bechara et al. 1995). Double-dissociations are patterns of findings showing that two functions operate separately from each other. For instance, if one species possesses metacognition but *not* theory of mind (ToM) and another species possesses ToM but *not* metacognition, then metacognition cannot simply be a by-product of theory of mind because it operates in ToM’s absence. Psychological studies have reported double-dissociations between conditioning and declarative knowledge (Bechara et al. 1995); item and source memory (Glisky et al. 1995); verbal and quantitative mathematical knowledge (Dehaene and Cohen 1997); and emotional and cognitive empathy (Shamay-Tsoory et al. 2009).

Plaut (1995) criticizes double-dissociation studies on account of fallacious neurobiological assumptions. His conclusion is that double-dissociations do not always indicate adaptive modularity. Among his evidence are instances in which single brain lesions produce double-dissociations in behavior, i.e., between processing of concrete and abstract lexical items.

Ongoing uncertainty exists as to whether capacities such as religious behavior (e.g., Wiebe 2008; Powell and Clarke 2012), artistic sensibility (e.g., De Smedt and De Cruz 2012), and the female orgasm (Puts and Dawood 2006; Lloyd

2009; Wallen et al. 2012) are best thought of as by-products or adaptations. An “adaptation” approach might consider ritualized behavior in the form of religious rituals as a costly signal that promotes/facilitates social cooperation and therefore confers adaptive advantage to the religious group (Sosis and Alcorta 2003; Bulbulia and Sosis 2011). Conversely, a by-product approach might suggest them to be epiphenomena of a Hazard-Precaution (H-P) system (Boyer and Liénard 2006). In this case, the by-product approach accounts for their widespread and compelling nature by suggesting that elements of religious rituals (e.g., themes) cognitively capture the H-P motivational systems, and from a cultural selection perspective, this set of human dispositions (i.e., H-P systems) could be considered an enabler of cultural transmission of particular mental representations (religious rituals).

Puts and Dawood (2006) suggest that the hallmarks of adaptive utility are found in the female orgasm. They hypothesize multiple adaptive phenotypic features: discriminative utility in mate selection; assistance in sperm uptake; selective retention of sperm; regulation of uterine contractions during intercourse; etc. Lloyd (2009) counters that the by-product hypothesis remains more likely because of the magnitude of variability in the female orgasmic response, which stands at odds with a strong directional selection account.

Another noteworthy example is Pinker’s (1997) contention that humans’ appreciation for music is a by-product of the more generalized design of the reward system. According to his account, music simply hijacks the brain’s reinforcement mechanisms like a drug. To make his reasoning clearer, he likens the appreciation of music to appreciation of high-fat foods, such as cheesecake, that were not featured in the environment of evolutionary adaptedness; in this account, both contain “megadoses of agreeable stimuli which we concocted for the express purpose of pressing our pleasure buttons.” Thus, the propensity to take pleasure from musical compositions is likely a by-product of the human reward system’s wiring, just like enjoyment of cheesecake. It is untenable that humans evolved to seek cheesecake in the early human environment (see

EEA relevance criterion, described above), and although it is a less clear-cut example, Pinker believes that music co-opts surrounding adaptations in a similar way.

This view is not unanimously shared among evolutionary psychologists. Miller (2000) contends that music performance bears the hallmarks of a sexually selected adaptation: complexity, clear reproductive significance, and elements of repetition/consistency alongside novel/spontaneous elements.

Relative Importance Across Fields

While most subdisciplines of psychology do not directly discuss the question of adaptation versus by-product, the implicit conclusions of these frameworks speak to the relative emphasis on adaptive and by-product explanations. In particular, Skinnerian behaviorist approaches often view a multitude of human traits as by-products of domain-general learning mechanisms. Among Skinner's arguments is the contention that human language is simply a complex form of domain-general reinforcement learning (Epstein et al. 1980). Chomsky (1971) famously criticized Skinner's account, mostly on the grounds of the *complexity* criterion for identifying adaptations.

More general debates on the importance of by-products in human psychology are ongoing. Gould and Lewontin (1979) criticize the evolutionary tradition for overemphasizing adaptive explanations of behavior and ignoring the ubiquity of by-products and exaptations, while Buss et al. (1998) respond to this criticism by highlighting the field's accepted standards of rigor in distinguishing adaptations from by-products (see section "[Identifying By-Products](#)" above).

The relative extent of by-products' importance in generating human behavior, cognition, and affect likely falls somewhere between the extremes suggested by behaviorist and cognitive approaches to the matter; however, such a question can and should be addressed with parsimony and consistent standards and evaluated on a case-by-case basis.

Conclusion

While by-products are often not the principal focus of evolutionary psychologists' investigations, understanding these phenomena and how they fit into the larger evolutionary picture is of crucial importance. In the present report, the clues that are often used to distinguish by-products from adaptations have been discussed; these include evolvability, reliability, efficiency, economy, precision, functionality, and complexity (Buss et al. 1998). While these variables provide a useful rubric for the classification of psychological traits into by-product and adaptation categories, their direct application to many specific cognitive and behavioral functions is a source of ongoing debate.

The paths of evolution – both the constraints and the opportunities – must be largely set by the size and nature of this pool of potential exaptations. Exaptive possibilities define the “internal” contribution that organisms make to their own evolutionary future. (Gould and Vrba 1982, p. 13)

Definition

An adaptation (sensu product) is an inherited and reliably developing trait that came into existence through natural selection because it helped to solve a specific problem of survival or reproduction

better than alternative designs existing in the population during the period of their evolution (after Buss et al. 1998). More specifically, “[c]haracteristic *c* is an adaptation for doing task *t* in a population if and only if members of the population now have *c* because, ancestrally, there was selection for having *c* and *c* conferred a fitness advantage because it performed task *t*” (Sober 2000, p. 85). The primary/original usage causing an adaptation to evolve is called a “function.” Much-cited examples of physiological and behavioral adaptations in various animal taxa include hibernation, echolocation, and thanatosis, whose main functions are energy conservation, navigation/foraging, and anti-predation, respectively.

By-products of adaptations include a range of phenotypes (i.e., an individual’s morphological characteristics, physiological responses, behavioral patterns, and psychological traits) whose origins, maintenance, and transformation are structurally and necessarily coupled with the evolution of adaptations, by way of historical constraints. There are two main by-products of adaptations: spandrels, and exaptations. Neither have any functional design: they did not originate as fitness-enhancing solutions to ancestral adaptive problems *during* their period of evolution. They only came about through the correlated selection of adaptations, and not because they were, themselves, *originally* selectively advantageous – even though, in the case of exaptations, they may have acquired a fitness-enhancing role at any point *after* their period of evolution.

Spandrels, also known as fitness-neutral by-products of adaptations, are *selected* (i.e., they arise through natural selection), but not *selected-for*, by-products of *selected-for* phenotypes (Gould and Lewontin 1979). They have never been, and are still not, adaptive. The chin, male nipples, and female orgasm are generally considered textbook examples of anatomical and physiological spandrels because they are non-adaptive developmental side effects of the selection for reduced mandibles in modern humans, the strong selective pressure on females to have functional nipples, and naturally selected male orgasmic capacities, respectively.

Exaptations are initially unselected traits capable of being subsequently put to (a new) usage through a process called “co-option” or “co-optation” (i.e., functional recycling of ancestral structures). An exaptation is a trait that was not originally designed and selected for its current usage, but owes its fitness-enhancing capacity to features present for other reasons, and is therefore *aptus* (i.e., “fit” in Latin) “by reason of” or “as a consequence of” (i.e., *ex-* in Latin) its form (Gould and Vrba 1982). The prefix *ex-* indicates that the trait’s quality of being *aptus* is posterior to its origin. Therefore, an exaptation is a trait that is currently adaptive without being an adaptation. Because the current (or recent) capacity of an exaptation to enhance fitness did not contribute to the original selection of this trait, the fitness benefit the trait is “exapted to” cannot qualify as a function. The (secondary) usage causing an exaptation to evolve is called an “effect” (i.e., its later/current usage; Gould and Vrba 1982). Typical morphological exaptations are feathers and fontanels, whose respective effects are flight in modern birds and easier parturition in placental mammals. Often-cited examples of behavioral and psychological exaptations in humans and non-human animals include ritualized behavior patterns as non-signaling phenotypic adaptations co-opted into communicative signals, as well as some linguistic components and religious belief as fitness-enhancing and culturally maintained by-products of specific cognitive adaptations.

Introduction

We are all familiar with the term “adaptation.” Most evolutionary scholars believe they can confidently define it and provide a host of examples of how biological evolution produced phenotypic traits that currently enhance the survival rate and reproductive success of their bearers. However, what does careful and critical scientific inquiry tell us about this level of confidence? When faced with evolutionary puzzles, such as clearly nonadaptive unfused skull sutures in reptiles and birds, what did we really learn from Darwin’s (problematically teleological) concept of “pre-

adaptation,” later renamed “exaptation” by Gould and Vrba (1982)? While paleobiologists rely on fossilized tissues or organs to test the correspondence between structural and functional components of extant and extinct species in their respective current and reconstructed ancestral environments, how can ethologists and evolutionary psychologists determine the phylogenetic origins and historical pathways of behavioral and psychological characteristics that do not leave systematic traces in the fossil record? What were the external selective pressures (i.e., adaptive problems) and internal factors (i.e., structural constraints) that were responsible for designing phenotypic adaptations and (re-)shaping their subsequent by-products over evolutionary time?

Answering these questions is a daunting task that requires (1) a solid understanding of the variety of evolutionary processes, products, and histories, (2) a strong evolutionary epistemological framework (e.g., testing specific, falsifiable, competing, and theory-driven hypotheses, with logical arguments, critical thinking, and scientific skepticism), (3) a healthy dose of Darwinian pluralism and the will to take evolutionary by-products seriously, (4) a conceptual and methodological toolkit including a number of complementary evidence-based criteria, (5) the humility to use these tools on a case-by-case basis, as there are no general rules to test hypotheses about “adaptations” versus “evolutionary by-products” that are applicable across phenotypic traits, species, and environmental conditions, and (6) a constant fight against our pervasive psychological predisposition toward teleological stories (Andrews et al. 2002).

In this review, I will strive to eschew the oversimplistic, flawed, and even counterproductive pan-adaptationist position, which consists in perceiving natural selection as the only force of evolution, minimizing the role of historical constraints on optimal designs, and believing that adaptations are ubiquitous. I will draw on different research fields (e.g., evolutionary biology, evolutionary psychology, evolutionary linguistics) and provide a series of examples of morphological, physiological, behavioral, and psychological traits whose evolution could be construed in terms of either adaptationist or

by-product accounts. I aim to show that a focus on by-products of adaptations can truly further our understanding of Darwinian evolutionary processes and the diversity of phenotypic outcomes they produce, including those with no obvious current survival or reproductive values.

Morphological By-Products of Adaptations

One of the basic tenets of Darwinian evolution holds that selection strength and phenotypic variability are negatively correlated. Therefore, one can expect that more functionally constrained phenotypes were subjected to higher selection pressures during their evolution, which should have made them less structurally variable than their less/nonfunctionally constrained counterparts, which are presumed to have evolved under weaker selection. Thus, comparative structural analysis of adaptations and their corresponding by-products may allow evolutionists to assess their relative functionality. Theoretically, this powerful structure-function interface could be applied to any pairs of behavioral traits that are linked at the proximate levels (i.e., in their developmental trajectories and underlying mechanisms) and at the ultimate levels (i.e., in their functional consequences and phylogenetic pathways).

Penis Versus Clitoris and Female Versus Male Nipples

This evolutionary-based prediction was tested in humans by examining two pairs of sexually selected morphological traits shared by both sexes, with one being an adaptation and the other being the corresponding developmental by-product. Within each sex, researchers compared interindividual variability in the size of penises versus clitorises, and the size of female nipples versus male nipples, after controlling for other morphological and environmental factors. As expected, the variability in the size of penises across men was significantly lower than that of clitorises across women; this result (1) is consistent with the fact that the former organ is an

adaptation and the latter its functionless developmental by-product, and (2) lends some support to the by-product account of female orgasm (Wallen and Lloyd 2008). However, contrary to expectations, the size of female nipples (i.e., the anatomical adaptation naturally selected for lactation) was significantly more variable than that of male nipples (i.e., the functionless developmental by-product); this result seems to discredit the premise that greater structural variability indicates weaker selection, and lower, or lack of, functionality (Kelly et al. 2018). Nevertheless, one should expand this type of investigation beyond morphological traits and variation in size. For example, one should test this hypothesis in other phenotypic traits (e.g., behavior patterns) and other types of structural variability (e.g., temporal organization of behavioral sequences).

Human Chin

Due to historical constraints within highly integrated body plans, many other morphological structures seem to have evolved as by-products of naturally selected organs. The human chin is typically considered a structural spandrel; it is an unselected-for but inevitable side effect of the construction of adjacent adaptive features that were designed to serve the combined functions of breathing, chewing, and talking, which required a reduction of our hominid ancestors' jawbone. Even though the human chin did not originate to solve any particular fitness-related problems in our ancestral past, experimental evidence suggests that sexual selection may have subsequently acted upon this morphological trait as a potential signal of health and mate value (Thornhill and Gangestad 1996). This example illustrates the multitude of fitness-enhancing phenotypic traits that were not originally built by natural selection for their later or current usages.

Human-Like Manual Proportions

Likewise, the evolutionary transition from ape-like to human-like manual proportions (with a long thumb relative to other fingers, allowing for our unique pad-to pad precision grip capability) has first led researchers to argue that the functional design of human hands originated as a fitness-

enhancing solution to the adaptive problem of tool-assisted extractive foraging. In other words, human-like manual proportions must have initially evolved as an adaptation for stone tool-making. However, this adaptationist hypothesis was ruled out after examination of the manual fossil remains of *Australopithecus afarensis*, a taxon that already showed human-like manual proportions but did not make or use stone tools (Alba et al. 2003). An alternative explanation (possibly combined with pleiotropic constraints) is that, once the selective pressures of arboreal locomotion were relaxed, finger reduction in *Australopithecus afarensis* could have emerged as a functionless by-product of the adaptation to bipedalism, and was subsequently co-opted in more recent hominins as an exaptation for stone tool-making (Alba et al. 2003).

Physiological By-Products of Adaptations

Antibacterial Enzyme and Lactose-Production Regulatory Protein

Just as evolution tinkers with preexisting structures, it also recycles physiological systems through functional shifts over time. Gould and Vrba (1982) provided a good example of such exaptational capacities across animal taxa. The body secretions (e.g., mucus, saliva, tears) of all vertebrates contain an enzyme called lysozyme that was originally selected for its antibacterial function; more specifically, this ancient molecule appeared around 500 million years ago and probably evolved as an adaptation for the dissolution of the mucopolysaccharide structure of bacterial cell walls. Around 350 million years ago, the genes coding for lysozyme underwent minor mutational alterations that gave rise to a new gene coding alpha-lactalbumin, a protein required for the synthesis of lactose, the sugar secreted in milk. During the even more recent evolution of mammals, when the need for a milk-producing system arose, natural selection simply operated on a preexisting molecule whose structure had already been modified and was co-opted for a new fitness-enhancing usage: Alpha-lactalbumin

was recruited as a by-product of an antibacterial adaptation to serve the effect of lactation in mammals.

Female Orgasm

The evolution of female orgasm has long been used as a case study in the highly debated logic of research questions pertaining to physiological by-products of adaptations. A comprehensive review of the literature showed the existence of 21 hypotheses about how female orgasm had evolved (Lloyd 2005). On the one hand, an overwhelming majority of them (i.e., 20) hold the view that this trait is an adaptation. An often-cited adaptive explanation is grounded in the “Female Choice” hypothesis, which states that a woman mating with more than one men over a period of time, possibly across different menstrual cycles, will experience orgasm preferentially with the higher-quality males. This hypothesis also assumes that female orgasm is accompanied by a mechanism of uterine upsuck that increases the chances of the female of being impregnated by the higher-quality male. However, while the first component of this scenario (i.e., female orgasm preferentially with high-quality males) has been fairly supported by empirical evidence, the second component related to fitness enhancement (i.e., preferential insemination by higher-quality males via uterine upsuck) has been refuted (Lloyd 2005). Moreover, ten of the adaptive explanations operate on the assumption that women experience orgasm frequently during sexual intercourse, whereas replicated questionnaire-based surveys of very large samples showed low rates of female orgasm during the most common and evolutionarily relevant sexual encounters (i.e., vaginal intercourse) (Lloyd 2013).

On the other hand, the “By-Product” hypothesis is the only non-adaptationist account for the evolution of female orgasm. Just as female nipples are adaptations, whereas males get nipples “for free” (due to developmental pathways that are common to both sexes), male orgasmic capacities were selected-for (because they served the function of facilitating sperm ejaculation), whereas female orgasm evolved as a functionless by-product of the physiological adaptation

counterpart in males, by virtue of developmental homologies between the penis and clitoris (Symons 1979). Importantly, the “By-Product” account for the evolution of female orgasm is not just a “null” hypothesis, as often negatively labeled by adaptationists to signify a by-default explanation that would be merely based on null results or non-supported predictions from the selectionist camp. Instead, it is a positive alternative causal hypothesis that can have independent empirical evidence in its favor. There is actually converging data to support it, including good to excellent evidence for (1) developmental homologies between orgasmic tissues shared between men and women, (2) lower interindividual variability in penis size than in clitoris size, (3) heritability of variation in female orgasmic capacities, (4) no significant correlation between the frequency of female orgasm and fitness (measured by more or healthier babies) in the context of multiple male partners, (5) cross-culturally low rates of female orgasm during vaginal intercourse, (6) effectiveness of female masturbation in producing clitoral orgasm, and (7) physiological responses (e.g., vaginal muscular spasms, body rigidity) and behavioral changes (e.g., ambivalent facial expressions, rhythmic expiration vocalizations) characteristic of orgasm in female non-human primates engaging in heterosexual and homosexual mounts (Lloyd 2005, 2013; Wallen and Lloyd 2008).

As the aphorism goes, “absence of evidence is not evidence of absence.” However, in this particular case, there is evidence for non-selection of female orgasm and no orgasmic function (*stricto sensu*) in women. Even though some women may find the by-product explanation for female orgasm demeaning, there is no scientific reason to consider it an underrated version of an adaptation. Many behavioral adaptations turn out to be morally questionable traits (e.g., some forms of homicidal behavior), whereas many evolutionary by-products are valuable in their own rights (e.g., artistic behavior). Female orgasm is not an evolutionary “best-of-a-bad-job.” Some cultures value this trait because it is associated with positive emotions and pleasure, not because of its evolutionary origins. Still, in an attempt to

rehabilitate the “By-Product” hypothesis for the evolution of female orgasm, Lloyd (2013) proposed to rename it the “Fantastico Bonus” account. In evolutionary terms, a bonus is a non-adaptation (i.e., fitness-neutral trait) that shows utility (i.e., it is helpful during an individual’s lifetime; Linde-Medina 2017). By providing sexual pleasure to women without increasing their reproductive success, female orgasm would qualify as a bonus.

Neuroplasticity

Neuroplasticity is the capacity of neural circuitry to modify itself structurally and functionally throughout ontogeny in response to environmental changes, experience, aging, and injury/pathology. As is the case with other types of phenotypic plasticity, evolutionists agree that neuroplasticity is adaptive, and evolves – it has increased throughout hominin evolution – through natural selection; however, they disagree on whether neuroplasticity itself is an adaptation, and thus a selectable trait (i.e., a direct target of natural selection, independent of the mean value of a trait across environments), or a by-product (i.e., an indirect/emergent property) of the selection on the different phenotypic optima produced via adaptive neuroplasticity and expressed in each separate environment (Via 1993). Proponents of the former/adaptationist view argue that neuroplasticity is under its own genetic control (i.e., there must be a specific set of “genes for neuroplasticity”) and genetically heritable, whereas proponents of the latter/by-product view claim that the same genes affecting the mean phenotype in each environment also affect neuroplasticity.

According to Buller (2005), “[. . .] rather than slowly adapting specialized structures in the brain to environmental demands over the course of evolutionary time, selection has designed a brain whose adaptation is its ability to adapt to local environmental demands throughout the lifetime of an individual, and sometimes within a period of days, by forming specialized structures to deal with those demands” (p. 142). In other words, neuroplasticity would be a domain-general adaptation allowing our brain to tailor domain-specific

solutions to domain-specific environmental problems. In contrast, Skoyles (1999) considered neuroplasticity an exaptation (1) arising from pre-existing neurophysiological/psychological adaptations, (2) being recently (i.e., “in a period too short for natural selection to have operated”) co-opted for “enabling brains evolved for life in simple hunter-gatherer bands to live in agricultural and high-tech complex societies,” and (3) resulting in “early humans developing the rudiments of a material and symbolic culture” (p. 439). This by-product view of neuroplasticity may contribute to solving the puzzle of the evolution of modern human cognition, including culturally beneficial mental skills that natural selection could not have anticipated (e.g., reading, vehicle-driving, chess-playing, computer-programming), but may be explained in terms of “exapted learning mechanisms” (Andrews et al. 2002).

Behavioral By-Products of Adaptations

Here, I will treat behavior patterns as selectable phenotypic traits – even though evolutionary psychologists typically consider they are not adaptations or by-products per se, because only the behavior-control neuropsychological mechanisms that produce them can be. The literature in various behavior-based disciplines (e.g., ethology, behavioral ecology, evolutionary psychology, anthropology) contains a myriad of examples that qualify as behavioral by-products of adaptations. In humans, these include (1) artistic behavior as a by-product of our adaptive capacities to over-perceive patterns and experience feelings in our environment (i.e., psychological adaptations such as an hyperactive agency-detection device or emotional processes), (2) force-copulating as a by-product of our male hominid ancestors’ adaptive sexual desire for sexual variety without long-term investment and adaptive generalized use of coercion to achieve goals in other behavioral domains, and (3) alcoholism as a by-product of our primate ancestors’ adaptive capacities to perceive the relative ripeness of fruit and predict their caloric value based on ethanol content.

Behaviors such as creating/enjoying arts, rapping, and over-drinking alcohol probably arose by co-opting cognitive processes and satisfying desires that were originally selectively advantageous in ancestral fitness-relevant contexts. Even though they serve no *function*, they might be culturally selected-for or selected-against in our modern world, and have beneficial or costly *effects* (e.g., pleasure/relaxation or harm/punishment), which would make them (mal)exaptations.

Play

Because play behavior seems purposeless in its immediate expression, biologically costly, but adaptive in its deferred benefits, it represents an evolutionary conundrum. There are many adaptationist hypotheses (e.g., sensori-motor training, preparing for the unexpected), and non-selectionist accounts (e.g., incidental side effect of surplus energy, functionless by-product of adaptive but hyperactive reward systems) for the evolution of play. In line with the exaptational view of neuroplasticity, Pellis et al. (2015) argued that, at a rudimentary/origin-relevant stage of evolution, “primary-process play” (i.e., incipient and fitness-neutral playful behavior patterns that are voluntary, repeated, rewarding, incompletely functional in the context expressed, and initiated under relaxed environmental circumstances) arose as a by-product of fortuitous conditions, adaptive or not (e.g., high metabolic energy, motivational conflict, boredom). Once evolved, these basic playful behavioral elements, characterized by some quirkiness, arbitrariness, redundancy, flexibility, and latent potential (i.e., core features of creative and adaptive variability – which is a postulate of biological evolution), would serve as a built-in reservoir of behavioral variants subsequently co-opted for beneficial/fitness-enhancing behavioral effects (i.e., an exaptation Type 2) during further evolutionary transformation into more elaborate secondary- and tertiary-process play.

Consistent with the aforementioned structure-function interface applied to pairs of morphological traits, a comparative analysis of the temporal organization of behavioral sequences expressed in two types of activities that are presumably linked at the proximate and ultimate levels, namely

object play and tool use, showed that the former was more structurally variable than the latter (i.e., its functional behavioral counterpart; Cenni et al. 2020). This result suggests that object play (i.e., a spandrel of some adaptive developmental processes) can serve as a pool of behavioral variability, and has the exaptive potential to be later co-opted for the fitness-enhancing usage (i.e., effect) of tool use.

Non-conceptive Sex

To explain the evolution of non-conceptive sex in animals, including humans, adaptationist and by-product accounts abound (Vasey 2007). In certain populations of Japanese macaques, adult females exhibit bisexual behavior: they routinely mount both adult males and adult females. Vasey (2007) proposed that, in this primate species, female-female mounting (FFM) and female-male mounting (FMM) are non-conceptive sexual behaviors that are functionally and evolutionarily linked, with FFM being an evolutionary by-product of a purported behavioral adaptation, namely, FMM. The functional hypothesis holds that FMM is a special courtship behavior, or a super sexual solicitation, that serves the function of focusing the male’s attention, preventing him from moving away, and expediting male-female mounting (MFM), in the context of high female competition for male mates. FFM would have evolved as a fitness-neutral by-product of selection for FMM, with a potential utility/bonus: Females could obtain sexual reward during mounts.

This model received some support (1) at the proximate/mechanistic level – the temporal organization of heterosexual mating sequences with FMM (i.e., the hypothesized adaptation) showed more structural signatures of functional constraints than that of heterosexual mating sequences without FMM (Gunst et al. 2020) – and (2) at the ultimate/phylogenetic level – an inter-group comparative study showed there were groups of Japanese macaques with FMM and no FFM, but no groups with FFM and no FMM, as expected if FFM was the by-product of FMM (i.e., the purported behavioral adaptation) because the latter should be more phylogenetically primitive than the former (Leca et al. 2014).

Language

The origin of language is one of the most puzzling mysteries in human evolution. Various adaptationist accounts have been proposed (e.g., “hunting coordination,” “grooming/gossiping,” “courtship,” “motherese” hypotheses; Számadó and Szathmáry 2006), but none has provided compelling evidence to attain wide acceptance.

Alternatively, converging behavioral, psychological, and neuroanatomical/physiological evidence support the by-product “Cognitive Coupling” hypothesis, which holds that complex stone tool-making and language co-evolved in early hominins, and the emergence of some linguistic components (e.g., basic syntactic rules) was facilitated by the “cognitive exaptation/hijacking” of preexisting brain mechanisms selected for hierarchical planning and sequential motor execution in the adaptive context of stone tool production (Kolodny and Edelman 2018). Indeed, systematically chipping away at a rock and building a coherent sentence are both goal-directed hierarchically organized sequential behaviors that require us to think several steps ahead. As *Homo erectus* was learning to make increasingly sophisticated stone tools (e.g., Acheulean hand axe), evolutionary changes in its brain could have paved the way for the evolution of language.

Changes in the linguistic components of modern languages (e.g., lexical items, grammatical features) are also explained in terms of exaptation, whereby “junk” morphemes may lose their original grammatical function over time, but remain “idle” for linguistic tinkering until they can be opportunistically co-opted for new/original grammatical effects (Lass 1990).

Ritualized Behavior Patterns

Like the exaptational recycling of feathers in ancestral and modern birds, serving multiple effects (e.g., sexual display, flight, water-shaders during fish-foraging) after their original function (i.e., thermoregulation), ritualization is a process by which non-signaling behavioral adaptations (e.g., breathing patterns, locomotory movements, foraging techniques, self-grooming) are subsequently co-opted for various fitness-enhancing

signaling usages in other contexts, and become exapted communicative signals (Weible 2012). For example, the pup-to-mother mouth-licking behavior as a feeding adaptation in wild canids – that functions to stimulate a regurgitation reflex, causing the mother to vomit food for her pups – was secondarily recruited for its submissiveness-signaling effect between subordinate and alpha wolves (i.e., first exaptation) and recently reused as a sign of affection between domestic dogs and human owners (i.e., second exaptation).

Ritualized signals also arose as behavioral by-products of adaptive “displacement activities” that were structurally modified by natural selection to enhance their effects. In ancestral situations of motivational conflict (e.g., fear/arousal), displacement activities were incomplete/unstructured, inefficient, and/or context-irrelevant behavioral sequences that served the function of internal pressure releaser via motor outlet (e.g., preening, self-scratching, yawning). Through ritualization, these behavioral adaptations were further exaggerated, repeated, stereotyped, or simplified, and thus exapted to more conspicuous and less ambiguous signals in diverse animal taxa, including humans (e.g., agonistic/sexual displays, vocalizations, gestural signaling, rituals) newly expressed in various contexts of communication (e.g., contest competition, courtship, anti-predatory tactic, group-decision voting, social bond-testing, praying ceremonies). The evolution of ritualized behavior patterns (like other phenotypic by-products of adaptations) is typically studied by conducting cross-species or cross-cultural comparative studies.

Psychological By-Products of Adaptations

According to Gould and Vrba (1982), the exaptational power of the human brain is immense. The “cognitive coupling/exaptation/hijacking” hypothesis (also known in neurophysiology as the “cultural recycling of cortical maps” hypothesis) holds that our extraordinary neuroplasticity and cultural capacities allowed us to co-opt preexisting cognitive adaptations or

spandrels for (new) fitness-enhancing/reducing usages (i.e., effects) or fitness-neutral utilities/bonuses through the emergence of various psychological by-product traits that are relevant to a range of domains in our modern cultural environments (e.g., notational/value/belief systems, technology, economy, arts) or are conceived as mental disorders (e.g., ADHD, depression, schizophrenia).

Even though the religious system may be a culturally evolved adaptation designed to solve the problem of cooperation in large human groups, the dominant position in the field of Cognitive Science of Religion (aka “Standard Model”) consists in viewing (raw) religious beliefs as functionless by-products of the adaptive cognitive architecture of our mind, originally designed by natural selection to solve fitness-related problems in non-religious contexts. These domain-specific psychological adaptations (or “functionally specialized computational devices”) from which the building blocks of religious beliefs and rituals (e.g., animistic bias, credibility-enhancing displays) arose include neocortical systems associated with hyperactive agency detection (e.g., pareidolia), intuitive ontological expectations (e.g., folk physics, folk biology, folk psychology or “theory of mind”), teleological reasoning, attachment, and contamination avoidance. Simply put, humans believe in gods because they are (false) pattern-detecting, cause-inferring, purpose-seeking, and story-telling animals. In a Darwinian pluralistic view, a new exaptationist model aims to integrate selectionist and by-product hypotheses of religion (Davis 2017). In the same vein, Burghardt (2018) outlined the intertwined evolutionary pathways of three by-products of adaptations reviewed herein: playfulness, ritual(ization), and belief.

Conclusion

The quest for adaptations and the demonstration that a given trait originated to serve a specific function, and thus solve survival or reproductive problems in humans’ evolutionary past, are part of the mission statement of evolutionary

psychologists. However, as stated by anthropologist David Stump (2010): “Those who hold to the idea that adaptation is the premier outcome of the all-encompassing process of natural selection will recognize the importance of the various types of exaptation and non-aptation as the “raw material” of evolution” (p. 16). In a more colloquial, maybe provocative, but equally powerful way, historical linguist Roger Lass (1990) wrote: “Historical junk, in any case, may be one of the significant back doors through which structural change gets into systems, by the re-employment for new purposes of idle material” (p. 98). This review aimed to stress that by-products of adaptations should not be considered the ugly ducklings of evolutionary research. Adaptations and their by-products are two complementary sides of the same evolutionary coin.

Let us not forget that an individual is an integrated and structurally constrained aggregate of adaptations, along with a heterogeneous class of by-products of adaptations (e.g., spandrels, exaptations Type 1, exaptations Type 2) and residues of evolutionary noise. The question of whether a specific phenotypic trait belongs to one of these three major categories, or is the outcome of a sequential combination of these products over evolutionary time, is generally open to rough debates (e.g., adaptationist versus by-product scenarios for the evolution of menopause, senescence, phenotypic plasticity, language, play, rape, homicide, and religious belief). In Roney’s (1999) view: “Distinguishing adaptations from by-products will require evolutionary psychologists to accept the challenge of empirically demonstrating evidence for special design. [...] A more rigorous union of evolutionary psychology with cognitive science may make arguments for exaptations and by-products largely academic” (p. 436). Yet, Andrews et al. (2002) carefully reminded us about the scientific value of skepticism: “[...] in the absence of evidence one way or another, we should be agnostic as to whether a given trait is optimally designed or constrained; exapted to a particular effect or specially designed for it” (p. 500).

To test “evolutionary by-product” hypotheses in humans, a promising way forward may lie in

the complex connections between biological and cultural evolution. The intriguingly rapid evolution of modern human cognition – which appears to challenge a strict and relatively slow adaptational schema – can be partly explained by inferring our species' dependence on a two-way process of evolutionary flexibility/plasticity (Coessens 2006). First, the unique and far-reaching exaptational features of the human brain have opened up an almost infinite reservoir of behavioral and cognitive possibilities, allowing our hominid ancestors to cope with increased environmental variability and resource uncertainty characteristic of the Pleistocene epoch. Over the past two millions years, members of the genus *Homo* exhibited evolved adaptability, which resulted in a surge of cultural creativity, including technological, symbolic, and artistic innovations. Second, such a culturally scaffolded landscape has provided *Homo sapiens* with enhanced affordances (i.e., a range of opportunities for actions offered by the environment), which in turn, have contributed to selecting further evolutionary flexibility in the next generation in some kind of ratchet-like effect. This cumulative bio-cultural evolutionary process has led to incremental changes as well as behaviors, beliefs, and artifacts with cultural histories, and that no individual could have invented on its own. Ultimately, by-products of adaptations have played a key evolutionary role in the ecological and demographic success of our species.

Altruism between relatives; Hamilton's Rule;
Kin-altruistic behaviour

Definition

The cost of an altruistic act to the donor must be less than the benefit, weighted by relatedness, to the recipient.

Introduction

How is an altruistic act favored by natural selection if it incurs a cost to the actor? As the behavior would have a detrimental impact on the actor's reproductive success, the genes that facilitate the expression of that behavior would be less likely to be passed on and should decrease in the gene pool. Hamilton (1964) recognized the importance of the

relatedness coefficient in the evolution of altruism, incorporating it in a formula to explain kin-selected (Maynard Smith 1964) altruistic behavior.

Imagine a scenario where an individual sacrifices its own life to save others. One copy of the kin-altruistic gene is lost from the gene pool when the actor dies, but if ten close relatives are saved as a result of the sacrifice, several copies of the kin-altruist gene are saved, increasing its frequency in the population. As long as the fitness benefit to the recipients, weighted by their relatedness, outweigh the fitness cost to the actor a kin-altruistic gene will proliferate. This is known as Hamilton's rule (Hamilton 1964):

$$C < R * b$$

where C stands for the cost to the actor, b represents the benefits to the recipient(s), and R is the relatedness coefficient. Thus a self-sacrificing altruistic act should be favored if it saves the lives of more than two brothers/sisters ($R = 0.5$), more than four nieces/nephews ($R = 0.25$), or more than eight first cousins ($r = 0.125$). This is, of course, an oversimplistic view of the link between a gene and a behavioral act; nonetheless, it is a useful concept to illustrate the principle behind Hamilton's rule.

The rule applies to any kind of altruistic behavior, and although it is well supported in nonhuman animals (e.g., Bourke 2014), evidence in humans is scarce (Burton-Chellaw and Dunbar 2015). One

of the difficulties lies in accurately, and ethically, calculating fitness costs and benefits for an appropriate altruistic act. The benefit, measured in terms of the increase in the relative's weighted reproductive success as a result of the altruistic act, must outweigh the cost to the actor, in terms of their decrease in reproductive success. There's no point, for example, helping a sister, if the help does not enable her to have more children while simultaneously preventing the helper from having one or more children of their own. Under these circumstances, the gene for sibling-altruism would not spread.

Conclusion

An altruistic act can evolve through kin selection, as long as the costs associated with the behavior are less than the benefits that accrue to the recipient(s), weighted by their relatedness. This is known as Hamilton's Rule (Hamilton 1964) and has been widely supported in the zoological literature. Evidence from human studies is relatively scarce, in part due to methodological difficulties and ethical considerations in designing appropriate studies.

Definition

Inferring the probability of starving to death from historical data.

Introduction

In prehistory and in historic times, humans have been at risk of such severe food shortage that they may starve to death. Such food shortages, largely in the form of long-term famines, may be due to natural conditions causing crop failure, economic or political policies, war, or combinations of these. This risk of famine is thought to have acted as a selective pressure on human physiology and cognition in determining the storage of food in the body, mainly energy in the form of fat. Various hypotheses including the thrifty genotype hypothesis explain humans' susceptibility to becoming obese due to this selective pressure (Wells 2009). Researchers have attempted to assess whether food shortage and the consequent risk of starving to death has provided sufficiently strong selective pressure to cause the high levels of obesity (Prentice et al. 2008; Speakman 2006).

Mortality Risks and Rates

Formally, "starvation" is the process of consuming insufficient calories to maintain body weight, rather than starving to death. However, for clarity herein "starvation" is intended to convey *mortality* due to insufficient calories over a sufficiently prolonged period.

The risk of starvation can be most simply calculated as the probability of dying from starvation per person per year. More properly, this is called the *rate* of starvation, since a *risk* is something that *might* happen, whereas a *rate* is events per unit of time. The rate of starvation is used to assess the selective pressure for animals, including humans, to store fat. There has been debate about whether this pressure has been sufficiently large to cause obesity in contemporary populations (Prentice et al. 2008; Speakman 2006).

The magnitude of a selective pressure relates not to the absolute magnitude (e.g., of mortality) but the variance in magnitude within a population. The extent to which the risk can be altered by mitigating adaptations is key. The risk of starvation is the rate that would be realized if there was

no mitigation. Humans are clearly adapted to mitigate the risk of starvation: this is the main role of body fat. Logical argument shows that since there is mitigation, the starvation rate cannot be used to measure the starvation risk (McNamara and Houston 1987).

Since not all people are as obese as physically possible, there is clearly some selective pressure that causes lower fat storage. Even obese people tend to defend a certain level of fat: rarely do people just carry on getting heavier indefinitely. Ecologists consider that animals are lean because the risk of being killed by a predator exerts a pressure (Houston et al. 1993). This can happen in one of two ways: carrying too much fat causes the animals to be slower or less able make fast evasive action because of their weight, or increased weight incurs greater energetic costs leading to increased need to forage thereby increasing exposure to predators (Witter and Cuthill 1993).

In the latter case the downwards pressure may not be from predation, but any risk associated with greater food consumption, such as the risk of eating poison or getting a serious infective disease. For clarity herein the selective downward pressure on reserves will be referred to as predation risk. This is a cost that is paid all the time, whereas the starvation only occurs during famines. We are interested in the long-term risks, which are calculated over a long time period. For instance, ignoring the sequential nature of survival for clarity, if a famine occurs once every 10 years and the probability of dying during a famine is 10%, then the starvation rate is 0.01. On the other hand, if predation rate is 1% per year every year then the predation rate is also 0.01.

The evidence from animals suggests that the rate of predation is always higher than the rate of starvation (Collins and Kays 2011). Wild animals rarely starve to death, because they do increasingly desperate things as they get hungrier which will lead to greater predation risk. This is why animals that are killed by predators are leaner than the general population, an observation that at first sight appears to contradict the assumption of body reserves increasing predation risk (Speakman 2018). Similarly, humans in famines

eat more and more risky things (toxic or rotting food stuffs). Therefore, the total mortality during a famine could be calculated and then compared to normal conditions to calculate the increase in mortality rate due to the famine, although most deaths are not due to starvation and so do not reflect starvation risk.

Models of the trade-off between starvation risk and predation risk in determining energy storage reveal a counter-intuitive insight: that there need not be any association between starvation risk and starvation rate (McNamara and Houston 1987). These models assume that animals, including humans, are adapted to these risks and have an appropriate store of fat to minimize the total mortality rate. Starvation risk is likely to decline quickly as fat is stored and then level off. Predation rate increases with stores, but the shape of this function is challenging to measure. This is unfortunate, because it has a critical influence on the effect of the starvation risk (Fig. 1). If predation risk is concave (accelerating) as body weight increases, then an increase in starvation risk

causes an increase in starvation rate. However, this increase is not proportional because of the adjustment in the adaptive level reserves. If predation risk is convex (decelerating), the starvation rate is predicted to *decrease* if the risk increases. This occurs because the position of the minimum total mortality rate depends not on the magnitude of the two risks, but on their slopes. Specifically, the minimum total risk is where the magnitude of the two slopes are equal (and opposite sign). Furthermore, if the predation risk is constant with respect to reserves, then the starvation rate is predicted to be constant with respect to the starvation risk.

Hence, increasing uncertainty of the food supply or rate of famines may increase reserves and so increase the predation rate. It is even possible that in some circumstances the probability of starvation may increase as food availability increases. Thus, the observation that most mortality, even during famines, is not from starvation is not evidence against the role of the risk of starvation in determining fat storage strategies.

Calculating Starvation Risk, Fig. 1 Mortality rates as a function of the investment in energetic reserves in two cases, showing that starvation *rate* may increase or decrease in response to an increase in starvation *risk*. The red lines show the starvation rate, green lines the predation rate, and blue lines the total mortality rate. The grey lines indicate the optimal investment in reserves, where total

mortality is minimized. The dashed lines show rates under low starvation risk and solid lines under high starvation risk. When predation rate is accelerating (left panel), an increase in risk leads to an increase in rate. On the other hand, when predation rate is decelerating (right panel), an increase in risk leads to a *decrease* in rate. Based on the analysis of (McNamara and Houston 1987)

Even the total mortality rate does not increase in a linear manner with the starvation risk. Since there is mitigation, the historical rate of mortality from food shortage cannot be used to measure the risk of starvation. We conclude that the magnitude of the mortality during food shortages, including famines, is uninformative about selective pressures, without additional information about the other selective pressures on body reserves (Higginson et al. 2016). Therefore, further debate on this issue is unlikely to help assess explanations for obesity.

One alternative explanation for the high level of fat is that the risk of starving may be negligible whilst food shortage still impacts on evolutionary fitness, such as by reducing fecundity due to the decrease in body fat (Prentice et al. 2008), as humans are partially capital breeders (women store fat to supply pregnancy and lactation). This could be explored further, although it is not clear how it might apply in men.

Conclusion

The number of people who have starved to death in human history cannot provide a measure of the strength of selective pressure to store body fat. Any risk of starving is likely to lead to selection for fat storage, as well as various other functions of body fat.

Definition

A phenomenon whereby organisms avoid detection or recognition by resembling the general background or specific objects therein.

Introduction

Camouflage is a phenomenon, which hides or prevents something from being noticed. As an umbrella term, it covers all strategies involved in concealment including prevention of detection and recognition (Stevens and Merilaita 2009). Camouflage exists across many biological taxa and provides among the most remarkable examples of adaptation. For example, cuttlefish (*Sepia officinalis*) can adjust their appearance in terms of color and patterning to match their respective visual habitat, but also change their shape to increase resemblance to natural objects such as coral, stones, or seaweed (Hanlon et al. 2009). Likewise grouse, ground-dwelling birds, avoid being seen by potential predators by closely resembling the background on which they nest (Thayer 1896). Despite being an ubiquitous anti-predator strategy in nature, and important in many areas of human application (e.g., military, hunting, test cars), only recently has science moved from descriptive accounts to test what camouflage

types exist, how they work, and what their adaptive value is (Nokelainen and Stevens 2016). There has been a revival in the study of camouflage among scientists spanning molecular, sensory and evolutionary biologists, visual psychologists, computer scientists, and art historians. Although camouflage can function via any sensory modality, here we outline the most extensively studied one: visual camouflage in animals.

A Short History of the Study of Camouflage

After Charles Darwin's hallmark book *On the Origin of Species by Means of Natural Selection*, much of the background in terms of what types of camouflage exist in nature was concluded prior to the 1950s. Three bodies of work were (and still are) particularly influential: *The Colours of Animals: Their Meaning and Use Especially Considered in the Case of Insects* by Edward B. Poulton (1890), *Concealing-Coloration in the Animal Kingdom: An Exposition of the Laws of Disguise Through Color and Pattern* by Gerald Thayer (1909), and *Adaptive Coloration in Animals* by Hugh Cott (1940). Since then the theory of camouflage has been refined particularly from the perspective of being an effective anti-predator strategy (Ruxton et al. 2004; Stevens and Merilaita 2011). These excellent accounts have made camouflage a textbook example of natural selection and a long-standing model system for understanding adaptation. Moreover, we know that being able to hide has been important from the very early days, as the earliest organisms bearing a coloration that suggestively served a camouflage function date back to marine animals in the Cretaceous period. However, it has proven challenging to quantify camouflage in natural settings (i.e., difficulty to quantify something that is hard to detect or recognize) and to understand how animals may appear to the appropriate receivers' perceptual systems (i.e., difficulty of seeing world through other animals' eyes).

How Different Types of Camouflage May Work

An organism that is hard to detect is cryptic. The best-known form of this is background matching, whereby both the color and pattern of the organism closely resemble visual properties of the background (Endler 1978). For example, the appearance of many nocturnal moths closely resembles the tree trunks on which they rest during daytime. Disruptive coloration, in contrast, is distinguished by high contrast elements that break up the body contour (Cuthill et al. 2005). The conspicuously striped patterns make an animal harder to detect or recognize in its respective visual environment. Detectability can also be reduced through countershading, whereby an object is darker on the surface facing higher light intensity (Rowland et al. 2007). The pale underside combined with a dark above side seen in many mammals reduces the obviousness of a shadow casted by the animal's own body (i.e., self-shadow concealment). This may also conceal the three-dimensional form of the body (i.e., obliterative shading). In aquatic environments, where there is no background to match, camouflage could be achieved through transparency, where light transmitted through the body renders the bearer virtually invisible. The silvering flanks of many species of fish may function as camouflage too (Ruxton et al. 2004). The scales construct a reflective surface that hinders detection or recognition because the vertically aligned scales operate like tiny mirrors, thus letting its bearer blend in with scattered light. Masquerading organisms (e.g., decorator crabs, stick insects) share a resemblance to inanimate objects that are typically of no interest to a predator (Skelhorn and Ruxton 2010) such as twigs, leaves, or stones (or even bird droppings). Although categorizing different types of camouflage is a useful exercise to understand how they may work, it is important to acknowledge that they are not mutually exclusive and should be considered as a continuum of a set of adaptive traits (Fig. 1).

Advantages of Camouflage in Nature

Predation is one of the strongest selective pressures in nature. Camouflage confers increased survival benefits to prey either during vulnerable life stages or during the whole life of an organism. Early work on camouflage, such as classical work on grove snails and peppered moths, underlined the importance of background resemblance. Grove snails (*Cepaea nemoralis*) carry pale shells on grasslands, whereas snails from shaded woodlands carry darker shells. These differences in shell shading are plausibly caused by divergent bird predation on different colored appearances for better background resemblance in a given light environment (Cain and Sheppard 1954). Similarly, peppered moths (*Biston betularia*) were among the earliest well-documented examples of how camouflage brings survival benefits to its carrier. Peppered moths have two color morphs: pale and dark. The appearance of the pale morph resembles more deciduous, light-colored tree trunks, whereas the dark morph matches the background best when resting on tree trunks darkened through pollution. Foraging bird predators can find mismatched moths on the tree trunks more easily, which facilitates increased matching to specific background types (Kettlewell 1955). It is important to remember that camouflage may also grant benefits to predators, particularly to those who ambush their prey, to which camouflage allows increased foraging success by getting close to their prey. For example, felid coloration often resembles that of the respective habitat's vegetation. By closely resembling the surrounds, these large carnivores are ought to be better able to approach the prey unnoticed before engaging the final pursuit to catch the prey (Caro 2005). Recent studies have quantified camouflage and its adaptive value more directly than classical accounts. It has become possible to quantify how likely an individual is to be attacked with respect to how closely the animal resembles its background as seen through the eyes of ecologically relevant receivers (Kelber et al. 2003). When detailed information of the receivers' vision, light conditions and color

Camouflage, Fig. 1 Illustrative examples of different camouflage types in nature. *Top left* is a rock ptarmigan, a grouse bird, which resembles its background, but also has disruptive markings. *Top right* lion cubs show the general resemblance to the background. *Middle left* is a common shrimp illustrating transparency, and *middle right* is a ghost

crab, which matches its background. *Bottom left* is a green shore crab, which resembles its background, but also has strong contrasting markings to break up the body shape. *Bottom right* a dolphin, which has countershading to mitigate its own body shadows (All photos by Ossi Nokelainen)

properties of the organism, and the background are obtained, the match to the background may be quantified. For example, a recent study of ground-nesting plovers demonstrated that nest survival in the wild is dependent on the degree of camouflage of the eggs (Troschianko et al. 2016). In

plovers, parents flee the nest early when a predator approaches, leaving the nest and the eggs vulnerably exposed on the ground. In contrast, in birds like nightjars that sit tight on the nest even when a predator is close, nest survival is dependent on the level of match of the adult plumage.

How Plasticity and Behavior May Facilitative Camouflage

Coloration is not a static property and some animals may change their appearance over time (Stuart-Fox and Moussalli 2009). In fact, some animals achieve background resemblance through color change. Many taxa are capable of this ranging from insects and crustaceans to reptiles and amphibians. Perhaps most impressively, cephalopods can change body coloration within seconds by using specialized pigments in their skin under neural control (Hanlon et al. 2009). However, color change is slower than this in most animals. For instance, marine crustaceans shed their carapace as they grow, and it has been shown they may adjust appearance between molts for better crypsis (Stevens et al. 2013). Also behavioral plasticity can be used to enhance the camouflage. Many animals can choose backgrounds that match their own coloration better. Quail hen chooses substrates for nesting that provide better match their own egg colors (Lovell et al. 2013). Moths adjust their body orientation and position after landing on a tree to decrease visual detection (Kang et al. 2012). Blue-footed boobies (*Sula nebouxii*) change their egg colors by rolling them in dirt, which increases the background resemblance and decreases nest predation (Mayani-Parás et al. 2015). Decorator crabs adorn themselves by attaching pieces of objects such as seaweeds on their skin that increases the resemblance to the environment (Nokelainen and Stevens 2016). The Pacific tree frog (*Pseudacris regilla*) exhibits color pattern-mediated microhabitat selection so that, in the presence of predator cues, individuals prefer a substrate that matches their own color (Wente and Phillips 2005).

How the Efficacy of Camouflage Links to Evolutionary Psychology

Beyond sensory capabilities, cognitive processes inevitably influence what makes an effective camouflage (Skelhorn and Rowe 2016). When contrasting color patterns are combined with

movement that exceeds the temporal resolution of the viewer's perceptual range, the colors appear to blend together (Stevens 2007). This physiological effect is known as flicker fusion. Movement may also create an illusion, which results in false interpretation of the direction and speed of the target, known as motion dazzle. Thus, variable stimuli have the potential to mislead animal's behavioral output. Similarly, predators have been demonstrated to be worse at finding camouflaged prey when prey populations are polymorphic (Bond 2007). This is because predators tend to focus on prey types that they have most recent experience with. The phenomenon is known as search image formation, which results in overlooking the rare morphs by predators. The followed evolutionary mechanism is known as negative frequency-dependent selection, which can maintain polymorphic prey by fluctuating morph frequencies (Gray and McKinnon 2007). Learning and cognitive processes may thus have a major effect on the value of different camouflage strategies. It is possible that predators learn some types of camouflage more quickly than others, especially the ones with high contrast markings. The value of a given type of protective coloration therefore depends not just on initial detection but also on experience and cognition.

Concluding Remarks

Despite being intuitively easy to understand, camouflage has proven difficult to study in natural settings. We still have a relatively limited understanding on the survival advantage that different types of camouflage provide to wild animals. Although categorizations are useful in order to understand how different forms of camouflage work, they may not be mutually exclusive. Recent technological advantages allow for tests of more detailed hypotheses regarding camouflage in more natural settings, taking into account animal cognitive processes and sensory stimulation across different modalities. Excitingly, we are about to understand how animals may see the world and how this may shape the preservation of the

avored forms in the struggle of existence. This will expand our understanding on camouflage and the diversity that has succeeded over the course of time on inherited characteristics under natural selection.

Growth; Neoplasm; Tumor

Definition

Cancer is a family of diseases unique to multicellular animals that are characterized by the uncontrolled cell growth and proliferation.

Introduction

In 1971, US president Richard Nixon declared the “war on cancer,” predicting victory within 5 years. More than 40 years later, cancer is still the leading cause of death in economically developed countries and the second leading death in developing countries. Despite major progress, the treatments developed have not lived up to expectations and cancer research is now at a crossroads, requiring a shift in the way cancer is studied and treated. More recently, scientists have increasingly entered the fray from an evolutionary perspective towards cancer. This Darwinian approach provides scientists with a novel paradigm that permits them to identify mechanisms that drive natural selection among cancerous cells within the tumor.

Cancer Evolution

Evolution is a double-edged sword for multicellular life. Acting over millions of years at the level for population of organisms, evolution animated the intricate complexities necessary for hearts, brains and living creatures including human beings. However, when evolution acts at the cellular level within an organism, it can induce tumor formations.

The problem of cancer is as old as multicellular life. During the transition from unicellular to multicellular organisms about 1 billion years ago, there was selection at the organismal level for the collaboration among single cells to foster the fitness of the newly emerged multicellular individual. This collaboration entailed that each cell had to stop maximizing its own fitness to better propagate its shared genetic material. Cancer happens when somatic cells acquire mutations that stop promoting the fitness of the multicellular organism by increasing their own cell division or survival relative to normal cells. In particular, the hallmarks of cancer (Hanahan and Weinberg 2011) represent different types of breakdowns or “cheating” of the cooperation. One hallmark of cancer is uncontrolled cell proliferation and the circumvention of programmed cell-suicide (apoptosis). Aktipis et al. (2015) have called this a form of demographic cheating. Cancer is also characterized by the stimulation of blood vessels to supply the tumor with nutrients (angiogenesis). This is an example of economic cheating. At short time-scales, these cancerous cells are successful and form neoplasms that can eventually kill the parent organism. This explains the selection of many mechanisms to suppress cancer at the individual level, including tumor suppressor genes that regulate the growth of cells and the architecture of proliferative epithelia that reduces the number of cells vulnerable to neoplastic evolution. Although cells still compete and neoplasms still develop, these mechanisms result in tumors that normally occur only later in life, when our prime reproductive years have passed.

Why do cancer suppression mechanisms not involve complete tumor elimination? The explanation for some remaining vulnerabilities to cancer may lie in evolutionary trade-offs between conflicting levels of selection. One crucial trade-off for multicellular organisms is between restraining uncontrolled cell proliferation while upholding the ability to repair tissue such as wound healing. For tissue repair processes to be successful, cells must be able to proliferate and migrate to the injured site. They must also be able to form new blood vessels to nourish the repairing

tissue. These abilities are reminiscent of some of the hallmarks of cancer (e.g., angiogenesis). It follows that species with fast and effective wound-healing mechanisms, possibly as a consequence of proneness to assault and injury, may be more vulnerable to cancer. In support for this, Archie et al. (2012) documented that baboons with more effective wound healing are subject to more aggression. Another trade-off is between cancer and embryogenesis. During embryonic development, cells often migrate to form tissues and organs. To be able to migrate, embryonic cells go through the process called epithelial-to-mesenchymal transition (EMT). Research indicates that the EMT program is reactivated in cancer cells, which may enable them to metastasize. Trade-offs between reproduction, aging, and susceptibility to cancer have also been suggested (Aktipis and Nesse 2013). Overall then, these trade-offs imply that while we could have more effective mechanisms to suppress cancer, this may entail high costs for tissue repair, embryonic development, reproduction, and longevity.

Nowell (1976) was the first to propose that the transformation of normal cells into cancerous cells represents a form of Darwinian evolution favored by natural selection, a hypothesis for which there is now ample empirical support. Heritable variation of reproductive success in a population is sufficient and necessary to cause evolution by natural selection. Natural selection occurs on a cellular level because somatic cells acquire heritable variation through somatic mutation and epigenetic events, including mutations that affect a single DNA nucleotide and the gain or loss of entire chromosomes. This variation is heritable through mitosis, and any variants that confer a selective advantage will be selected, regardless of their ultimate effects on the host's health. In fact, all of the hallmarks of cancer are phenotypes that improve the fitness of a mutant clone over competitor clones lacking the phenotype. Each variant cancer cell can then further divide to form a clonal lineage. The daughter cells, in turn, may also acquire new genetic and epigenetic abnormalities in the process of cellular reproduction. Cancer is therefore a result of

repeated clonal expansion, succeeded by clonal selection, in the adaptive tissue ecosystem. The result is a better-adapted, highly heterogeneous cancer. Although this evolutionary progression to a cancerous state is most often stopped through cancer suppression mechanisms, a tumor can develop fast and aggressively if it acquires early mutations allowing it to evade apoptosis or the immune system.

Resistance to therapy is a major problem in the treatment of most cancers. While patients often respond to the first application of therapy, they are prone to relapse. Why has it been difficult to find a cure against cancer? An evolutionary perspective sheds light onto this question: cancer – even within one person – is not a single entity. New genetic evidence from cell genomics and single cell analysis in many different types of cancer supports the existence of extensive mutational heterogeneity among cancer cells (e.g., Merlo and Maley 2010). Marusyk and Polyak (2013) have argued that this heterogeneity enables a cancer cell population to deal with selective pressures. Cancer therapies impose an artificial selective pressure, eliminating sensitive cancerous cells but leaving behind resistant cells. In other words, cancer therapies are selecting for resistant tumor cells and selecting against chemosensitive cells. As a corollary, chemotherapy that kills chemosensitive cells may simply remove clonal competition and open up space and resources. This allows the resistant lineage to expand again, with often catastrophic consequences for the patient. High genetic diversity among cancer cells is therefore arguably a key determinant of therapeutic failure. Furthermore, since each patient's cells evolve through an independent set of mutations and selective environments, the emergent tumor cell population is probably unique within each cancer patient. This, in turn, means that it is extremely difficult to find a general treatment program that is equally effective for all patients.

While an evolutionary perspective highlights the slim chances for finding a definite cure for cancer, on the bright side, it also highlights the potential effectiveness of several treatment strategies. Below are some examples:

Early Detection and Intervention

Etzioni et al. (2003) have argued that early detection poses one of the most promising approaches to prevent the growing cancer burden. A cancer that does not have enough time to produce much genetic diversity is unlikely to contain treatment-resistant cells. Early detection of neoplasm before widespread genetic heterogeneity develops already plays a key role in the control of cervical and breast cancer and is likely to become more important for the management of colorectal, prostate, and lung cancer.

Combination Therapy

Even with early diagnosis and intervention, there will remain some cancers that evolve in a covert fashion and only present late in their evolutionary development harboring chemoresistant cells, as is the case with pancreatic cancer, glioblastoma, lung cancer, and many ovarian cancers. Some researchers have suggested that combination therapy should lead to improved response rates compared to single agent therapy and reduce the likelihood of relapse. Given that cancer therapeutic resistance is a result of different mutations within the cancer population, the likelihood is relatively high that at least some cells within a large tumor cell population will carry a mutation conferring resistance to a single agent. However, the odds that a patient has cancer cells with the multiple mutations needed for resistance to several different drugs is much lower. In support for this, a meta-analysis of single-agent versus combination chemotherapy found that the latter conferred an advantage for survival, tumor response, and time to progression in women with metastasis breast cancer. However, adding more drugs also increased toxicity, indicative of a trade-off between toxicity and blocking therapeutic resistance (Carrick et al. 2009).

Individualized Cancer Therapy

Given that every patient has a unique tumor architecture, not every drug (or combination of drugs) will work similarly in every patient. Consistent with this, a large number of patients treated for cancer do not respond to therapy given to them.

Some researchers therefore emphasize the importance of a personalized medicine approach where drugs are chosen based on the underlying mutations in each patient's tumor.

Mismatch Repair

In the broader context, some researchers have focused on environmental and life-history factors that may pose a risk to cancer because they are novel in an evolutionary sense. Darwinian natural selection has “no eyes to the future.” It follows that certain gene variants that were selected in the past, because they best fit the prevailing environmental conditions now, can increase cancer rates due to changes in the physiological context in which these inherent genes now have to function. In other words, there is a mismatch between ancestral conditions and modern environments. This mismatch is the result of our rapid evolution of social behavior patterns that has outpaced our Stone Age genetics. A potent example of evolutionary mismatch is with skin cancer. There is a general agreement that exposure to the sun and ultraviolet radiation (UVR) is the main causative factor in the induction of skin cancer. Dark, or highly melanized, skin acts as a defense against UV-induced damage. However, high amounts of protective skin pigment also restraints vitamin-D biosynthesis in places that receive less sunlight. This is the leading explanation for why paler skins have evolved in higher northern latitudes where contact to UVR has tended to be low. The migration of white-skinned individuals to southerly environments creates a mismatch between skin pigment and sun exposure, which explains why white-skinned individuals are orders of magnitude more at risk for skin cancer when living in equatorial zones.

In a similar vein, the most widely accepted evolutionary hypothesis for breast cancer, the hormonal proliferation hypothesis (Eaton et al. 1994), postulates that a major contributor to the increased risk for breast cancer is a dramatic change in life-history patterns that has skyrocketed women's contact to the endogenous steroid hormones estrogen and progesterone. Hunter-gatherer women had far fewer lifetime ovulation cycles compared to women living in

developed countries. This is because the former were usually pregnant or lactating, whereas later first birth, nursing of shorter duration, earlier menarche, the use of modern birth control, and fewer children born to modern women means fewer menstrual cycles in a lifetime. During menstrual cycling, the ovarian hormones stimulate breast cell division, enhancing the risk for mutations that lead to cancer. Overall then, appreciation of environmental and life-history factors can help prevent the development of cancer via the education of lifestyle decisions, or where these are difficult to change, as might be the case for breast cancer, via focusing attention on hormonal or immunological intervention.

Conclusion

In summary, viewing cancer through an evolutionary lens may help to gain a clearer understanding of cancer. In particular, an evolutionary perspective allows us to appreciate better why cancer exists (multicellularity), how it progresses (somatic evolution), why it is not more common (selection for cancer suppression mechanisms), why cancer suppression mechanisms cannot completely eliminate cancer (trade-offs), and why it is so difficult to cure (tumor heterogeneity), as well as opening up possible avenues for cancer treatment.

Definition

Family Canidae, a family within Carnivora with multiple species, including dogs, wolves, foxes, jackals, coyotes, and other dog-like mammals.

Introduction

Canines are an extremely large and varied family, including domestic dogs, but also wolves and foxes. The domestic dog is humankind's closest animal companion, having been domesticated for at least 15,000 years and possibly longer. Because of their close association with humans, whether they share our moral attributes is of high interest to researchers. Humans have the tendency to attribute many human mental states to dogs, including "secondary" emotions such as jealousy, embarrassment, guilt, shame, pride, empathy, and grief (Konok et al. 2015). Some of these are overly anthropomorphic and do not reflect the underlying psychology of dogs. For example, owners often report that their dog feels guilt over disobedience, whereas research suggests that dogs are actually displaying fear of punishment or trying to reduce punishment (Hecht et al. 2012; Horowitz 2009). However, dogs may actually feel jealousy (Harris and Prouvost 2014) and empathy (Custance and Mayer 2012). Whether dogs feel these emotions is relevant to morality, as these emotions can indicate a sense of morality.

Allchin (2009) breaks morality down into multiple levels: moral behavior, moral motivation or intent, moral systems, and moral cognition. Moral behaviors include altruistic behaviors (i.e., cooperation and helping). Moral motivations include sympathy, empathy, other innate motivations for helping, and emotions related to justice, including guilt, shame, and a sense of fairness. Moral systems are those social groups that enforce cooperation through reward or punishment. Moral cognition involves the ability to detect intentions (positive or negative) of others (theory of mind) in order to judge moral behaviors and attitudes, and the ability to keep track of the behaviors of others over time (such as reliability). This entry will discuss the moral behaviors, motivations, cognition, and systems of dogs and other canines in order to explore the evolution of morality in Canines.

Morality in Canines

Moral Behaviors

Of the moral behaviors that canines engage in, cooperation is probably the most ubiquitous.

Many species of canine engage in cooperative breeding, which occurs when individuals other than the parents help care for offspring, such as older siblings or unrelated group members (Wiley and Rabenold 1984). Cooperative breeding (regardless of the psychological modules designed to motivate it) is usually explained by kin selection (older siblings increase their fitness more easily by assisting in raising younger siblings rather than going out to find a territory and/or mate of their own), but there may also be direct benefits of staying with parents related to survival, such as for foraging or defense, and delayed benefits related to increasing chances of later acquiring a territory or mate (Wiley and Rabenold 1984). Unrelated individuals might benefit by reproductive access to the parents or breeding pair, as well as the direct benefits gained by kin (Wiley and Rabenold 1984).

Canines are unusual in that they are the only carnivore family that uses food regurgitation to provision young, with the exception of bat-eared foxes (Moehlman and Hofer 1997). Non-parents (alloparents) will provide food to both mother and pups and assist in guarding pups in dens; some actually assist by lactating as seen in red foxes and wolves (Moehlman and Hofer 1997). Others engage in communal nursing (i.e., Bengal foxes, bat-eared foxes, arctic foxes, gray zorros, red foxes, coyotes, African wild dogs, and gray wolves; Moehlman and Hofer 1997). Among smaller species, only females tend to alloparent, whereas in larger species both sexes will engage in alloparenting behavior (Moehlman and Hofer 1997). In general, the presence of alloparents in canines does seem to increase pup survival (Moehlman and Hofer 1997).

Likewise, many canines also engage in cooperative hunting, although this is limited mainly to those of larger body size (Moehlman and Hofer 1997). Black-backed jackals, golden jackals, coyotes, dholes, gray wolves, and African wild dogs engage in cooperative hunting (Moehlman and Hofer 1997). The benefits of cooperative hunting in canids are still unclear: cooperative hunting can allow the killing of larger prey, an increase in dietary breadth, and may have a higher success rate, but it is unknown whether

individual food intake increases with cooperative hunting (Moehlman and Hofer 1997). Domestic dogs can learn to cooperate with each other on a human-designed problem that mimics the reactivity of prey; food rewards were placed on the opposite side of a fence with two openings and a human experimenter controlled a sliding door that could close only one opening at a time. Although dogs cooperated, they did not monitor each other's actions in this task (Bräuer et al. 2013a).

Free-ranging dogs will cooperate in conflicts; members of one group will cooperate during aggression from or against strangers (Bonanni et al. 2010). In this case, dogs are more cooperative when they are part of smaller groups and the risk of defecting is higher (i.e., their individual contribution has a greater effect on the likelihood of winning or losing a conflict). However, there is no evidence that dogs punish those who "cheat" in this context. In addition, dogs cooperate with humans. Historically, dog domestication may have initially involved humans using dogs for assistance during hunting. In a study of modern moose hunting groups in Finland, researchers found that dogs increase hunting success in both small and large groups of hunters, especially when moose density is low (Ruusila and Pesonen 2004). Thus, dogs may have translated cooperative hunting skills from their wolf ancestors to hunting cooperatively with humans. Dogs also cooperate with humans today: dogs trained to work with blind owners as well as normal pet dogs will take turns initiating cooperative actions on an obstacle course (Naderia et al. 2001).

Recently, dogs have also been found to be cooperative to the extent of prosociality (i.e., helping others with no direct gains to the self). Dogs will help a human with a goal (e.g., pushing a button to help open a door) when humans explicitly point at a button or when they communicate verbally with the dogs (Bräuer et al. 2013b). To be clear, they perform these actions without specific training or without being given any food reward. Dogs even differentiate between generous and non-generous humans in an "eavesdropping" paradigm, using vocal cues to recognize cooperative intentions in humans (Marshall-Pescini et al.

2011). In addition, dogs behave prosocially towards other dogs that are familiar to them. When given the opportunity to manipulate a food-dispensing device, "donor" dogs will pull a bar to dispense food to another "receiver" dog, even when the donor receives no food (Quervel-Chaumette et al. 2015).

Another area where canines display moral behavior is through reconciliation. This has only been studied in dogs and wolves, but may also include other species of canines. Reconciliation falls into the category of post-conflict affiliative behaviors (i.e., friendly behaviors such as greeting, sitting/lying together, anogenital sniffing, playing, or licking), which can occur between victim and aggressor (reconciliation) or between victim and another dog (consolation or post-conflict third-party affiliation; Cools et al. 2008). These behaviors function to reduce the negative effects of aggression, such as having to leave a group (Cools et al. 2008). Dogs, like primates, show both reconciliation and consolation, especially towards familiar animals (Cools et al. 2008). These behaviors may not be new to dogs; wolves, both in captivity and in the wild, also show reconciliation and consolation, and tend to direct these behaviors towards other animals that give them coalitionary support (i.e., support during conflicts; Baan et al. 2014; Cordoni and Palagi 2008; Palagi and Cordoni 2009). In sum, canines show many behaviors that are considered to be within the sphere of morality, such as cooperation and reconciliation. However, the degree to which these behaviors are actually motivated by moral sentiments is unclear.

Moral Motivations

Domestic dogs may have *empathy*, the ability to understand and respond to other animals' emotions. Empathy can be a powerful motivator of moral behaviors in humans. Dogs are attentive to human emotional states; they gaze longer at humans when they are displaying happiness rather than sadness, even when these emotions are not directed towards the dog (Morisaki et al. 2009). In addition, other research has shown that dogs can make behavioral responses to different emotions

displayed by humans (Merola et al. 2014). When humans show either happiness or disgust after looking inside a box or around a barrier, dogs are much more likely to approach the box that was reacted to happily. However, this effect is not as strong with unfamiliar humans, suggesting that this may be a learned, rather than empathetic, response (Merola et al. 2014).

Outside of emotion reading, there is more direct behavioral evidence for empathy. Dogs are more likely to approach – and show more submissive behaviors when approaching – a crying person compared to someone who is talking or humming, and this effect holds for both familiar and unfamiliar persons (Custance and Mayer 2012). Dogs will even choose to approach and sniff, nuzzle, and lick a crying unfamiliar human instead of approaching their owner. This appears to be empathetic behavior, but the authors suggest it could be due to previous learning histories of being rewarded for approaching crying humans.

Another area of moral motivation that has been studied in canines is fairness. Domestic dogs appear to have a sense of fairness, although not in all situations. Dogs do not actually play fairly; role-switching for some behaviors do not occur during play, such as with mounts, muzzle bites, or muzzle licks, although dogs do take turns with chases and tackles (Bauer and Smuts 2007). However, dogs do have a sense of fair rewards; they display what is termed “inequity aversion” and show negative responses when rewards are distributed unevenly (Range et al. 2009). Dogs are quicker to start refusing commands when they receive no reward to a command that a partner had received a reward for, although they do not pay attention to the size of the reward or amount of work done, as primates do (discussed in Horowitz 2012). In addition, dogs prefer trainers who reward unfairly in their favor, giving more rewards to the subject than the partner, suggesting that dogs are more concerned with getting a reward than with fairness, *per se* (Horowitz 2012). Overall, dogs, and possibly other canines, do show some moral motivations, including some evidence for empathy (or at least emotion recognition) and a limited sense of fairness.

Moral Cognition

Moral behaviors may require several cognitive abilities, including good communication abilities, sensitivity to attentional states of other animals, and even theory of mind. Domestic dogs are excellent at communication with both humans and other dogs. As summarized by Kaminski and Nitzschner (2013), dogs can follow various types of human pointing (e.g., using a hand or looking in the correct direction) to retrieve food that has been hidden (usually in one of two locations, such as under cups or buckets) without evidence of learning during the experiment, suggesting that dogs come into the experiment understanding human pointing gestures. Dogs can follow points regardless of whether the human looks at the dog or the food while pointing, or even if the human walks away from the food location while pointing at it. Some dogs are able to use more subtle communicative gestures from humans to find hidden food, such as head turning, bowing and nodding, and even glancing towards food. They even seem to understand whether the gesture is intentional or not, as they ignore similar pointing gestures (such as looking at a watch to check the time) that are not accompanied by eye contact with the dog. However, they do not “eavesdrop” on informational gestures not directed towards them (i.e., when the human points at a hidden food location while looking at another human), even as puppies. Kaminski and Nitzshner (2013) suggest that dogs interpret these communicative cues as orders or instructions, rather than as informative. Indeed, dogs will even follow human points to search in locations that they already know via previous experience is not the location of the food. However, socialization is important; pet dogs and socialized wolves are better than shelter dogs at following pointing gestures (reviewed in Kaminski and Nitzshner 2013; see also Rooney et al. 2001).

Although dogs may learn to follow human communicative gestures during their lifetimes, even young puppies can follow human points, suggesting a role of domestication in selecting for dogs’ skill in reading human communicative cues. In addition, wolves that are raised by and

intensively socialized to humans can also use human communicative cues to locate hidden food, but they require more socialization and are generally outperformed by dogs when raised and tested under identical conditions. Likewise, domesticated silver foxes outperform non-domesticated silver foxes at following human points. Overall, many canid species can use human communicative cues and both domestication and socialization play a role in the development of these abilities. Along with using gestures to locate food, dogs also recognize specific play signals from humans (see Rooney et al. 2001). Moreover, dogs not only understand human communicative cues, they also communicate back with humans. As summarized by Kaminski and Nitzschner (2013), dogs will use gaze alternation (i.e., looking between humans and a desired, but inaccessible, object such as a toy) and vocalizations to communicate with humans, possibly intentionally. They persist with these behaviors until a desired behavior occurs in the human (such as retrieving the inaccessible toy for the dog). Overall, dogs are good at understanding human communications and communicating back to humans.

Canines also have good communication with other members of their own species. Most canines use body language and facial expressions to communicate emotion (e.g., fear, aggression), social status (e.g., dominance or submission), and motivations (e.g., readiness to attack, bite, flee, or play), with greater degrees and complexities of expressions found in more social species, such as wolves (Fox 1971). Most canine species also use vocal communications to communicate over longer distances, particularly in solitary species but with the exception of the wolf and coyote (Fox 1971). Domestic dogs appear to be sensitive to the attentional states of humans, particularly in understanding where their gaze is directed (see Kaminski and Nitzscher 2013, for review). Dogs are less likely to retrieve a “forbidden” treat when a human is watching them as opposed to the human having their backs turned, doing something distracting, having their eyes closed, or leaving the room. They also obey a “lie down” command faster and for longer when their

owners are facing them, rather than looking away or out of sight. In addition, they preferentially beg for food from humans who are looking at them, rather than humans who are looking away (reviewed in Kaminski and Nitzscher 2013).

Dogs also choose toys that humans are capable of seeing (as opposed to those hidden from a human, but not another dog) when given the command to retrieve a toy, suggesting that they are capable of taking into account a human’s visual perspective when making choices (Call et al. 2009). In a similar test, dogs did not distinguish between two hidden toys when the human had only watched one of the two toys being hidden, suggesting that they did not take the human’s *knowledge* into account (as described by Kaminski and Nitzschner 2013). However, dogs do appear to distinguish between humans who know where food is versus those who are just guessing where food is, even when the only difference between these two humans was where their eyes were pointing during baiting of food containers (Maginnity and Grace 2014). Overall, these results show a strong ability to understand and interpret human visual perspectives and attention, and possibly even their knowledge states. Some researchers interpret these results as showing that dogs have a theory of mind (i.e., that they understand the mental states underlying the behavioral states of attention and gaze). For example, in the forbidden treat paradigms, dogs might understand if a human *sees* you, and thus *knows* you are taking a treat. In the guesser-knower paradigm, dogs might understand that one human (whose eyes were pointed towards the containers during baiting) *knows* where the food is (Maginnity and Grace 2014). In both cases, dogs could be representing human’s knowledge states, rather than just interpreting their body or eye position. However, behavior-reading perspectives, where dogs associate certain behaviors with certain outcomes (like scolding, or being handed a treat) still cannot be fully ruled out (see Roberts and Macpherson 2011). Regardless of whether or not dogs actually have theory of mind, they appear to have sophisticated cognition related to responding to human behaviors.

Moral Systems

Canines do not appear to engage in any moral systems; there are no reports of punishment or reward of certain behaviors within groups of canines.

Conclusion

Canines overall show many behaviors that can be considered moral, such as cooperation and prosociality, as well as reconciliation. Such behaviors in canids may be motivated by empathy and possibly a sense of fairness, and may be controlled with sophisticated cognition related to communication and the attentional states of other animals. However, they do not have any moral systems enforcing such behaviors with reward or punishment, and thus they may not be moral in the sense that the canids themselves have a sense of morality.

Definition

Carruthers defines mental modules more loosely than does Fodor and provides three arguments in defense of the concept of massive modularity of mind.

Introduction

In *The Architecture of the Mind: Massive Modularity and the Flexibility of Thought*, Carruthers (2006) defends the concept of massive modularity of the human mind. He first distinguishes massive modularity (that the brain is composed entirely of modules) from Fodorian modularity (which postulated peripheral modules feeding into a domain-general central processor/s). He then provides a series of three formal arguments for the massive modularity of mind: an argument based on the architecture of complex biological systems; an argument appealing to task specificity, which is supported largely by comparative evidence; and an argument from computational tractability. The current entry summarizes Carruthers' position and notes some key challenges that his arguments have received.

The Nature of Modularity

Carruthers (2006) argues that Fodorian modules (Fodor 1983) are not consistent with a massively modular concept of mind that is "even remotely plausible" (Carruthers 2006, p. 6). Fodorian modules are conceived as domain specific (responding to information of a single class or domain, such as spatial information or visual information), have their own transducers (such as cone and rod cells serving a visual module), and are fast and automatic. Fodor (1983) conceptualized such modules as peripheral to a central processor, which he credited as responsible for reasoned thoughts, ideas, and beliefs (outputs which Fodor's modules could not achieve). Carruthers (2006), on the other hand, argues that a massively modular concept of mind stipulates that the mind is constructed *only* of hierarchically organized modules. As such, modules must be capable of any and all mental processes and outputs, including the most complex and sophisticated thoughts. Carruthers (2005) argues that mental modules are: dissociable (in that they can be changed without affecting the working of other mechanisms); functionally specific (serving a single

function, such as navigation, but using inputs from across Fodorian domains, such as both spatial and visual information); and localized within specific neural structures. In common with Fodor, though, Carruthers also requires a module's internal workings to be inaccessible to other modules, and to be mandatory, in that their processing cannot be voluntarily suppressed. Carruthers rejects Fodor's central claim that modules are encapsulated (i.e., that they cannot draw on information from elsewhere in the mind during the course of processing) in favor of a form of weak encapsulation, in which information from elsewhere in the mind is accessible but cannot be drawn upon all at once.

Wilson (2008) and Cowie (2008) charge that Carruthers' ideas, and in particular that the loss of the strong version of encapsulation, represent a weakened conception of modules. While this may be true, Carruthers (2008) argues that the goal of his book is not to extend the concept of Fodor modules to central processing functions of the mind but rather to identify the conception of modules that can most defensibly be extended to these central functions.

The Argument from Biology

The first of Carruthers' (2006) three arguments for massive modularity is the argument from biology. Quoting foundational work on the evolution of complex biological systems (for example, Simon 1962, see more recently Simon 2003) Carruthers observes that some level of modularity is a requisite for evolution by natural selection to produce incremental improvements in the functioning of a complex system. This is because random mutations must affect a reasonably small, and preferably related, collection of traits, such that when a random mutation produces an improvement to some (dissociable) component of the system (a rare enough event in itself), that improvement is not completely offset by deleterious effects on other components (the more common impact of a random mutation). He argues that the human mind is an evolved,

complex, biological system, and as such must exhibit a level of modularity.

In biological systems, this modularity is inherently hierarchical, with cells organized into tissues, tissues into organs, and organs collectively forming functional systems (such as the digestive system). Carruthers extends this feature to his description of massive modularity as well. Though he concedes that the hierarchy of mental modules could potentially be quite shallow, amounting to no more than a handful of dissociable modules, Carruthers argues that the complexity of the human mind reflects a massive proliferation of function (2005). In combination with Carruthers' assertion that modules map cognitive functions one-to-one, this implies a massively modular mind made up of a "*very great many*" modules (2005, p. 11).

This argument hinges on the proposition that modular systems provide more efficient and rapid solutions to cognitive problems than domain-general systems, which has been challenged by theorists in the past (Fodor 2000). However, Carruthers asserts that a domain-general central processor of the mind would quickly become overwhelmed and that weakly encapsulated, dissociable, and isolated modules are therefore a more efficient way of solving specific, recurring cognitive problems.

The Argument from Task Specificity

Carruthers' (2006) second argument proposes that the specificity of cognitive tasks with which a hypothetical animal must contend (using the azimuth of the sun to determine the time of day compared with the computations associated with dead-reckoning, for example) necessitates the existence of computationally specialized modules within animal minds. Carruthers invokes Gallistel's (2000) arguments to assert that no *general* learning mechanisms likely exist at all within nonhuman animals, with each distinct challenge an animal must solve, and skill it must acquire, supported by a specialized computational process. He refutes Samuels' (1998) proposition of an "informational

modularity.” This is where a nonspecialized central learning mechanism exhibits a proliferation of algorithms in response to different types of information. Carruthers argues that such a mechanism would become irretrievably overwhelmed and is in any case not consistent with the notion of parallel processing that predominates in modern theories of cognitive neuroscience. Although many of the arguments relating to task specificity are centered on comparative examples, they are tied to the human mind by an argument of common descent. It is curious that, unlike massive modularity of the human mind, Carruthers presents massive modularity of the animal mind as sufficiently uncontroversial and self-evident that it counts as *prima facie* evidence for the massive modularity of the human mind. If one accepts that massive modularity of mind, whether in humans or nonhuman animals, is a position that requires independent verification, this argument distills into a case of begging the question.

This argument also makes the assumption that the assumed modularity of animal minds has been maintained in the evolution of human minds (Wilson 2008). Carruthers accepts this point, arguing that since humans retain all of the animal mental capacities with some incremental additions, it may be assumed that these additions are also modular. However, it is possible that, even if the additions to animal minds are modular, a series of such additions could lead to the loss of modularity.

The Argument from Computational Tractability

Carruthers’ third argument is the argument from computational tractability. In this, he argues that cognitive processes are computational (i.e., the mind is the result of the computational properties of the brain). These computational processes must be sufficiently tractable that they are soluble within the human brain within a finite timescale. They must also, therefore, be frugal in the amount of information they utilize and in the complexity of algorithms they

employ. Such tractability, Carruthers argues, is only possible if the computational processes (and, by extension, the mental modules that house them) are at least weakly encapsulated (insulated from other modules), permitting them to draw only upon a predetermined set of relevant information from the rest of the mind. In making this argument, Carruthers acknowledges that the notion of a computational mind is a central premise of his version of massive modularity (and indeed a central premise of much of modern cognitive psychology). While he concedes that this is not an uncontroversial claim, Carruthers argues that computational processes offer the only feasible mode by which mental processes can be realized into physical ones – one of the few allusions he makes to the fact that theories of massive modularity of mind imply a level of mind/brain dualism that is not completely resolved.

Conclusion

In conclusion, then, Carruthers (2006) suggests a definition of modularity that is less tightly defined than that of Fodor (1983) but which allows for the central processes of the mind to be modular in addition to the more peripheral tasks proposed by Fodor (1983). Carruthers offers three arguments in defense of this conception of the mind as massively modular. Critiques of Carruthers’ position comprise claims that Carruthers modules are insufficiently tightly defined to represent a true massive modularity (Wilson 2008) and empirical disputes over the accuracy of the assumptions about animal minds and processing efficiency.

Definition and Inclusion

Casual sex and hookups are largely synonymous and involve sexual behaviors that occur outside ongoing committed relationships. These brief uncommitted sexual encounters occur among individuals that are not dating or romantic partners, and they are performed without any expectations of future romantic relationships. The encounter typically occurs only once but may cover a variety of sexual or physical intimate behaviors such as kissing and petting, intimate touching, oral sex, and intercourse. With regard to types of casual sex behaviors, operational definitions are more often inclusive than exclusive (Garcia et al. 2012). Kissing, petting, and intimate touching may all be central elements in casual sex encounters – and may often precede genital manipulation and intercourse – but the only reproductive relevant behavior is vaginal intercourse.

In studying casual sex from an evolutionary psychology perspective, we strongly advise researchers to make a clear distinction between nonreproductive and reproductive sexual behaviors and to specify the casual, brief, and non-committed characteristics of the encounter. To illustrate this, reviews of studies suggest that nearly all casual sex encounters (hookups) involve kissing; nearly six out of ten engage in sexual touching above the waist, half below the waist; and one in three performed or received oral sex or engaged in sexual intercourse (Garcia et al. 2012; Monto and Carey 2014). Women and men report largely equal participation in these behaviors, but men more frequently initiate sexual intercourse than women (Baumeister et al. 2001; Grøntvedt et al. 2015). Whether the sexes differ in their initiative for nonreproductive behaviors is not known.

In this chapter, we do not consider sexual infidelity as a special case of casual sex. Neither do we consider sexual subcultures, open relationships, or same-sex encounters. We define casual sex from an evolutionary psychology perspective as *noncommitted, short-term sexual encounters involving intercourse, and thus the likelihood of becoming pregnant*. We advise alternative and specific approaches to the understanding of brief, noncommitted, nonreproductive sexual behaviors.

Introduction

Casual sex has become more common among young adults during the past two decades, and this trend has been termed “hookup culture” (Monto and Carey 2014). Popular in contemporary Western culture, people are exposed to visual images of sex and erotica, and uncommitted sexual relations are frequently portrayed, suggesting higher acceptance for sex with no strings attached. This stands in stark contrast to pre-World War II Western culture norms of courtship and mating in that was guarded and supervised by parents (Garcia et al. 2012). The 1960s initiated a period of increasing sexual liberation and availability of oral birth control, but the public opinion and

acceptance toward casual sex during the 1960s were clearly more restrictive than today (ibid.).

Apparently, cultural changes as described above may affect peoples’ acceptance of, and involvement in, casual sex. However, evolutionary psychologists have suggested that changes in attitudes toward sex in general and casual sex in particular should be considered in the light of changes in operational sex ratio, OSR (Okami and Shackelford 2001), the *ratio of marriage-aged men to women*. The reason for this is that the availability of mates affects mate preferences and mate choices. In the years following World War II, the OSR fell down to its lowest level with only 75 available men for every 100 women in America in the mid-1960s (Okami and Shackelford 2001, p. 225). With low OSR, female dyadic power waned and female-female competition for mates increased, and women needed to lower their standards for mates, putting less emphasis on status and recourses. During the 1960s, the sexual revolution began in the USA, with increased rates of pre- and extramarital sex and out-of-wedlock cohabitations. It is unlikely that this change in sexual restrictedness would have occurred in a culture with high OSR (abundance of men).

The importance of OSR for sexual restrictedness in a culture is further sustained in cross-national studies. In a 48-nation study, Schmitt (2005b) reported less sexual restrictedness in nations with higher number of marriage-aged women relative to men (low operational sex ratio). This association was strong. Further, Schmitt (2005b) sustained that women’s sexuality appears to be less fixed and more affected by harsh and demanding reproductive environments than men’s sexuality (e.g., prevalence of infant mortality, low birth-weight, teenage pregnancy, and fertility rates). Schmitt (2005b) reported that the level of demanding environment was moderately correlated with national levels of OSR. As environments become less demanding, women, but not men, become more promiscuous. In harsh environments, women move toward monogamy, while men remain relatively promiscuous. However, in each of the 48 nations, men’s sexuality was less restricted

than women's, and even in Norway, one of the most secular and gender-equal nations, men's sexuality is found to be markedly less restricted than women's (Bendixen et al. 2017; Kennair et al. 2016). Finally, there is evidence that regional variations in scarcity of female mates across US states affect the level of sexual restrictedness in men and women as predicted by evolutionary theory (Kandrik et al. 2015).

Sexual Strategies Theory

Buss and Schmitt's Sexual Strategies Theory has contributed both new theoretical and empirical insight into the variations of human sexual behavior. Rather than describing mating as either strictly monogamous or promiscuous, the theory proposes that humans have evolved a complex collection of different mating strategies, both short and long term, which are activated differently depending on context. Humans have throughout their evolutionary history encountered different adaptive problems when engaging in a short-term strategy (e.g., one-night stand or affair outside an ongoing, more stable relationship) versus a long-term strategy (i.e., marriage) (Buss 1998). In addition, women and men have encountered different adaptive problems related to mating. As such, sex differences are expected in human sexuality and mating behavior. Our mate preferences and mating decisions are thus hypothesized to be products of selection pressures during ancestral conditions. The core focus of Sexual Strategies Theory is desire and the interpersonal consequences of desire leading to emphases on conflicts and harmony between the sexes, attraction tactics, and tactics to derogate competitors with regard to sexual relationships (Buss 1998).

A long-term strategy requires an assessment of future reproductive value of potential partners, whereas a short-term strategy requires sexual motivation to engage in sex with various partners and evaluation of immediate sexual accessibility in potential partners. As predicted from Trivers' theory of parental investment, men are expected to assign a larger portion of mating efforts toward short-term mating compared to women. The direct

benefit men can achieve by applying short-term strategies is mating with a greater number of fertile partners which could lead to more offspring. Women's primary benefit of short-term mating is the increased probability of mating with a man with good genes (Gangestad and Thornhill 2008). Given that the number of offspring does not relate to the number of partners as it does for men, indirect genetic benefits are hypothesized to be the ultimate explanation for why women have short-term sexual encounters. Shifts in preferences in short-term mating settings across the menstrual cycle, particularly near ovulation, are interpreted as in favor of such a view.

Predictors of Casual Sex

Sex and Age

Men generally report more sexual desire than women (Baumeister et al. 2001), they desire more sexual variety (Schmitt and 118 Members of the International Sexuality Description Project 2003), and men are more permissive toward casual sex behavior and casual sex attitudes (Schmitt 2005b). These sex differences rank among the strongest for psychological attributes. Men are also found to be far more willing to accept an invitation to having sex with a stranger when given the opportunity (e.g., Clark and Hatfield 1989). Still, women and men report largely similar involvement in casual sex within cultures, albeit the prevalence may differ largely between cultures. (E.g., prevalence rates from studies of sexual regret (Bendixen et al. 2017; Kennair et al. 2016) suggest that two out of three Norwegian male and female students have had casual sex. Comparably, in a US sample of students, 50% of males and 44% of females reported having had casual sex.)

As noted above, men initiate sex more often than women, but there is considerable intra-sexual variation with regard to initiative. The desire component of sociosexuality (SOI) is shown to increase in initiative to sex in both sexes, and men who score high on pleasure motivations for having sex report more initiative taking (Grøntvedt et al. 2015).

Casual sex has become more common in recent decades, particularly among young adults (Monto and Carey 2014), and those who have their first intercourse at a younger age might be more likely to engage in casual sex. Age at first intercourse may again be related to a number of environmental and genetic factors.

Alcohol and Other Substances

While sex in romantic relationships rarely happens after drinking (9%) and especially not heavy drinking (5%), alcohol use is much more typical before casual sex (Walsh et al. 2014). Walsh and colleagues found that 53% of the women in their study drank before casual sex and 38% drank heavily. The same study found that 15% of the women in the study used marijuana in association with a hookup, while only 3% of women used marijuana in association with intercourse in romantic relationships. LaBrie et al. (2014) also found an increased likelihood of hookups due to drinking – approximately 30% of the participants report that they would not have hooked up or gone as far physically if they had not been drinking. Further, self-reported alcohol intoxication symptomatology (e.g., loss of inhibition) but not frequency of alcohol consumption generally is shown to be a strong predictor of hookups involving intercourse in both male and female undergraduate students (Paul et al. 2000). Interestingly, findings from a study involving survey responses as well as experimental outcomes of mating context manipulations and binge drinking among young adults suggest that heavy drinking may function as a short-term mating strategy (Vincke 2017) and that men and women intended to drink more heavily when experimentally primed for short-term relative to long-term mating situations.

Sociosexuality and Other Personality Characteristics

A number of personality characteristics may be related to young adults' participation in casual sexual behavior. Sexually unrestricted individuals (scoring high on the sociosexuality inventory) who are clearly more short-term oriented are more likely to seek out partners for casual sex

due to (1) *prior involvement* in casual sex, (2) condoning attitudes toward casual sex, and (3) increased desires for casual sex (SOI-R; Penke and Asendorpf 2008). Possibly, sociosexuality plays a role in sustained casual sex behavior, as sexually unrestricted students report less regret following casual sex encounters (Kennair et al. 2016).

Further, attachment styles appear to be related to short-term mating and casual sex. In a 56-nation cross-culture study, Schmitt (2005a) found that insecure attachment was associated with short-term mating. Others have found that being adventurous and impulsive predicts more and harm avoidance predicts less frequent hookups with sexual intercourse (Paul et al. 2000).

Self-Esteem

A person's self-esteem has been found to be related to whether one is likely to hook up. One study found that male and female undergraduates with lower self-esteem and/or self-worth hook up more often and do more often have intercourse during hookups (Paul et al. 2000). Another study found that for women in particular, low self-esteem was strongly associated with a greater number of sex partners since puberty and in the past year, as well as for casual sex (Mikach and Bailey 1999). How self-esteem feeds into casual sex behavior and whether it is an outcome, or a predictor, of casual sex are not currently known.

Ovulation and Shifts in Desire and Mate Preferences

Women's preference for short-term mates around the days of ovulation seems to shift in the direction of physically attractive men who appear confrontational, arrogant, and socially respected (Gangestad et al. 2007). The shift in mate preferences across the menstrual cycle seems to be robust and in accordance with the good gene hypothesis, particularly for cues to genetic quality such as body masculinity and behavioral dominance (Gildersleeve et al. 2014). However, it remains to be shown that changes in preferences across the menstrual cycle affect casual sex *frequency* or that these changes correspond with changes in characteristics of the casual sex

partner. Furthermore, for *facial* masculinity, which has also been presented as a cue for good genes, findings are less clear-cut, and some controversy has arisen following recent meta-analyses and reviews. Despite ovulation being concealed, women appear to leak cues that may be picked up by men. One study finds that across the menstrual cycle, female strippers are found to receive more tips around days of ovulation compared to strippers using hormonal contraception (Miller et al. 2007).

Possible Outcomes and Consequences of Casual Sex

The US Centers for Disease Control and Prevention (CDC) lists several physical consequences of risky sexual behavior, including STIs and unwanted pregnancy. It is important to note that casual sex does not need to be risky in itself, as one may have casual sex while using condoms, but frequent casual sex increases risk. CDC in the USA only mentions casual sex among foreign travelers, which seems odd. Further, official statistics addresses unmarried pregnancy, but not casual sex.

Sexually Transmitted Infections (STIs)

Sexual activity is the major risk factor of contracting an STI, due to multiple partners and these partners' likelihood of also having multiple partners. The use of condoms would reduce such risk for penetrative vaginal sex. Still, statistics or studies on the likelihood of contracting an STI particularly related to casual sex behavior are lacking.

Unwanted Pregnancy

The risk of pregnancy is basically determined by ovulation and thus varies greatly across the menstrual cycle. Among women attempting to become pregnant, the likelihood of conception with a single act of unprotected random intercourse is approximately 3%, increases markedly on the days surrounding ovulation, and peaks to nearly 9% on day 13 of the menstrual cycle (Wilcox et al. 2001). The probability of

conception also varies with frequency of intercourse and is particularly high for daily intercourse during the days near the day of ovulation. Although studies of effect of ovulation suggest there is a shift in mate preferences for coupled women at mid-cycle, the authors are not aware of published data suggesting that women actually do have more casual sex around the days of ovulation, nor if there is an increased risk of pregnancy following casual sex.

In summary, there seems to be a need for increased research within the field of physical consequences of casual sex.

With regard to *psychological* outcomes, an obvious aim of casual sex is physical pleasure, although that is probably a little too simplified, as there are many different reasons for sex (Meston and Buss 2007). While a short-term sexual orientation is associated with pleasure reasons, a short-term orientation is also associated with reasons such as experience seeking and mate guarding (Kennair et al. 2015). Therefore, one needs to consider a broad range of outcomes of casual sex. Studies of positive emotional outcomes of casual sex are, however, surprisingly rare. This may be a sign of implicit moralism or sex negativity in the research community and may result in a potentially biased depiction of the effects of casual sex.

Likelihood of Orgasm and Pleasure

Although the sex differences in reported casual sex encounters are small or nonexistent, there are massive sex differences in the likelihood of achieving orgasm when having casual sex (Kennair et al. 2016, 2018). There are also large sex differences in how highly importance of orgasm is rated and how strong physical pleasure one felt during the most recent casual sex encounter (Kennair et al. 2016, 2018). These large sex differences in physical gratification due to casual sex encounters may be relevant when considering the two sexes' motivations for casual sex behavior.

Well-Being

In a paper considering sociosexuality, Vrangalova and Ong (2014) found that

unrestricted participants who had had casual sex reported higher well-being than those who had not. In a later study, Vrangalova found that respondents who indicated low levels of autonomy as a reason for hooking up reported poorer well-being. This is partly contrasted by Townsend and Wasserman (2011) findings, suggesting that even when women deliberately engaged in casual sex, they reported increased worry with increased number of partners – with opposite findings for men. There is reason, from a gene quality perspective on mate preferences and the relevance of such indicators for short-term sex motivation, to expect associations between casual sex and various well-being outcomes (e.g., anxiety, depression, and self-esteem). From a more liberal, sex-positive perspective, one might consider that sexual activity in itself might increase well-being as is often suggested for coupled sex. We found no published evidence of this aspect of casual sex effects.

Negative Postcoital Emotions

Sexual Strategies Theory predicts that there would be sex differences in negative emotions after sex. In a cross-national study, Fernandes et al. (2016) found, in line with earlier research (Campbell 2008), that women had more negative emotions related to the need for bonding, while men had more negative emotions related to avoidance of bonding (compare to ideal relationship outcomes of hookups below).

Regret

Regret is an emotional response to counterfactual cognitive processing. Women and men differ in their regret in relation to casual sexual encounters. A robust finding is that women regret having had casual sex more than men do, while men regret passing up casual sex opportunities more than women do (Bendixen et al. 2017; Galperin et al. 2013; Kennair et al. 2016). Regretting having had casual sex is associated with worry about sexual reputation in women, while unrestricted sociosexuality and greater sexual gratification are associated with lower levels of regret in both sexes (Bendixen et al. 2017; Kennair et al. 2016, 2018). Further,

these studies suggest that taking the initiative to casual sex was associated with lower levels of regret only for women, that feelings of disgust were strongly associated with higher levels of regret, and that religious beliefs were basically unrelated to regret.

Relational Outcomes

There seem to be large sex differences in ideal outcomes of casual sex, dovetailing findings on negative postcoital emotions. Such negative emotions probably arise when one does not achieve desired relational outcome. A recent study by Weitbrecht and Whitton (2017) considered both ideal, expected, and actual relationship outcomes after a hookup. About a third of the men would ideally end up in a romantic relationship, compared to more than 60 percent of women. On the other hand, approximately 38% of men would ideally like to continue sexual relations, compared to 16% of the women. Expectations differed from ideals: women expected to continue having sex more than their ideal indicated; both groups considered the likelihood greater for continuing having sex and lower for a romantic relationship. 22% of men reported actually ending up in a romantic relationship, and 47% continued having sex. For women the actual outcome was 24% in romantic relationships, and 26% continued having sex. The authors also found that approximately 40% of participants, across a 10-week period, achieved the relational outcome they desired from a hookup – including the categories mentioned above and categories “nothing more” and “friendship.”

Sexual Harassment

Findings from several studies of adolescents and emerging adults suggest that frequency of casual sex is positively associated with being sexually harassed (Bendixen and Kennair 2017; Skoog and Özdemir 2016). Casual sex frequency (the behavior component of SOI-R) also predicts sexual harassment of peers, over and above the effect of sociosexual attitudes and desire. The above effects are largely comparable for men and women.

Conclusion

From an evolutionary perspective, casual sex is noncommitted, short-term sexual encounters involving intercourse, and thus the possibility of conception. Sexual Strategies Theory maintains that humans have evolved a complex array of strategies for short-term and long-term mating. However, due to sex differences in parental investment, men are, relative to women, expected to assign more mating efforts to short-term mating. Hence, the sexual psychology of women and men is expected to differ markedly for mating that is emotionally detached and without any commitment such as casual sex. This is especially so, due historically to the risk of pregnancy and cost for women.

As predicted by Sexual Strategies Theory, overall, men have stronger preferences for casual sex, show more positive attitudes toward uncommitted sex, and desire casual sex far more than women. Individual differences in this personality dimension affect both sexes' willingness to have casual sex, as well as how casual sex affects well-being and feelings of regret when having had casual sex. Casual sex is common among young adults and associated with the intake of alcohol. However, casual sex may have some negative outcomes in terms of increased risk of STIs, unwanted pregnancies, or sexual harassment. Following casual sex, women report more negative emotions and regret than men, and women expect romantic outcomes of casual sex more than men.

Definition

Age categorization is the process of categorizing others or the self as belonging to a particular age group.

Introduction

The process of age categorization serves biological, psychological, and social functions by enabling us to deal with stimuli from the world around us more effectively. For instance, categorizing the self as belonging to a particular age group can inform and provide a meaningful social

identity, which is fundamental to how we define and see ourselves (Harwood et al. 1995; Tajfel and Turner 1979; Tajfel 1981). Perceiving others' age can inform our feelings and behavior toward them, and can underpin judgments about attractiveness, which is associated with reproductive success (Jokela 2009). In this entry, we draw on social psychological, cognitive, and evolutionary theories to provide an overview of categorization by age. After defining age categories or groups and providing examples of the subjective nature of their boundaries, we provide an overview of the cognitive processes underpinning how people perceive others' age, the biological and social cues used to estimate, and categorize others by age. We consider the function of age categorization, both as a way of classifying others to simplify the world around us and classifying ourselves to help define our own identity. We then explore the social psychological and behavioral consequences or risks of age categorization and how it underpins age stereotypes, age prejudice, and aged-based discrimination.

What Are Age Categories or Groups?

Throughout the lifespan, people define themselves and others in relation to the age groups they belong to and those we do not belong to, and people mark transitions between these groups with social occasions, such as birthdays or anniversaries. The practice of remembering and celebrating birthdays ensures that as we get older, the age we have reached becomes part of our identity (Bytheway 2005). However, instead of seeing age on a continuum based on chronological age, we segment the life-course into a series of discrete age categories such as baby, toddler, child, teenager, young adult, middle-aged, older adult, and elderly. These age categories are ascribed both descriptive (e.g., character traits) and prescriptive (e.g., expected behavior) attributes, which stem from a combination of maturation and biological aging processes, social structures that segment by age and age-based stereotypes.

Signs of maturation at younger ages and biological aging are used to determine which age group

people belong to, and are correlated with the attributes people associate with age groups. However, processes of maturation and biological aging are not solely reliant on chronological age; they vary according to many factors, including genetics, gender, poverty, and birth cohort (Arber et al. 2003). In addition, biological differences between age groups are often reinforced or exaggerated by social structures and widely held age stereotypes, which can prescribe different ways of behaving for different age groups. For example, compulsory education in many countries prescribes a period of deferred responsibility and participation in educational programs (Hagestad and Uhlenberg 2005). At the other end of the age spectrum, eligibility for the state pension marks out a time at which people might stop or reduce participation in the labor market. There are also laws that prohibit certain activities for younger age groups, such as restrictions on substance use (e.g., alcohol, cigarettes), employment, and sexual activity.

In addition to social structures, age stereotypes also convey descriptive and prescriptive norms for those within different age groups. *Stereotypes* are the positive and negative characteristics and behaviors believed to be shared by most people from a particular social group (Brown 2010). Age stereotypes can increase perceived differences between age groups, but can also increase the likelihood of actual differences in interests, abilities, and personal characteristics because stereotypes can be self-fulfilling in nature (Levy 2009; Lamont et al. 2015). Age groups, therefore, reflect not only generalized developmental differences between those of different ages, but differences that have been reinforced and exaggerated through social structures and stereotypes.

Variability of Age Categorization

Age categories vary in distribution (age range), size (number of members), and in the degree to which they overlap. Moreover, the use of age group labels is not always consistent and can vary by culture, context, and over time. For instance, extended life expectancy has increased the number of people living to the age of 100, resulting in a new age group, centenarians. In UK, centenarians are the fastest growing age group, with the number of

100-year-olds almost doubling over a 14-year period (ONS 2017). Some categorizations may have multiple labels (e.g., “senior citizen,” “retired,” “pensioner”), while in other contexts, there are more relevant role-related classifications (e.g., parent, child) and in some situations, a simple “younger” verse “older” categorization is sufficient. Finally, age boundaries (the age at which people transition from one age group to another) can vary depending on the individual and the context (Abrams et al. 2011).

Although we have category labels that define age groups, the corresponding ages associated with these labels are quite variable (Bytheway 2005). For instance, research on age categorization has consistently shown that the boundaries that define “old” and “young” are fluid. The 2008/2009 European Social Survey asked respondents from 29 countries in the European region to estimate the age at which people stop being described as “young” and the age at which people start being described as “old.” On average, respondents perceived youth to end at 40 and old age to begin at 62; this may mean that people below 40 and over 62 are more vulnerable to age prejudice and discrimination due to their perceived “young” or “old” age status, respectively. However, the placement of these boundaries varies by survey respondents’ own age, gender, and country, and by their own self-categorization (Abrams et al. 2011; Ayalon et al. 2014; Basleven 2010). Both perceptions of the end of youth and the onset of old age increased with respondents’ age. Women perceived the end of youth and onset of old age to be later than did men. The “end of youth” was viewed to be as early as 34 in Norway, but as late as 52 in Greece. The “start of old age” was viewed to be as late as 65 in Greece, but as early as 55 in Turkey (Abrams et al. 2011). In addition, relative to others of the same chronological age, respondents who categorized themselves as belonging to a younger age group also perceived old age to start later (Basleven 2010). This suggests that as people age, they continually redefine others in relation to their own age group, but also that age categorizations are influenced by social contexts and social constructions of age, which could differ between countries and cultures. However,

despite a high degree of subjectivity and flexibility in the application of age categories, categorization by age and estimating others' age happens ubiquitously.

How Do We Categorize by Age?

When we first encounter others, we automatically categorize them into social groups such as age, gender, or race (Brewer 1988; Brewer et al. 1981). In fact, age is one of the first characteristics we notice about people (Fiske 1998; Kite et al. 1991). Visual perception, biological indications, and social cues all contribute to the psychological processes of age categorization. In addition to categorizing others, we also categorize ourselves by age (Giles and Reid 2005), and this is partly why there is a degree of fluidity in the application of the categories.

Visual Perception and Estimation of Age

Definitions of our own age group and the age groups of others are informed by categorization processes and are cognitively represented as prototypes. Prototypes are meaningful representations of an ingroup member in relation to a given outgroup and are a typical or representative ideal of the category. Research on face perception shows that a prototypical image is held in a physical location in the brain known as the fusiform face area (FFA) of the fusiform gyrus. The FFA recognizes and processes the location of facial features, such as the eyes, nose, and mouth, in relation to one another (Liu et al. 2010). This representation is then passed on to other regions of the brain for interpretation and assessment, such as the occipital face area (OFA) and the ventral anterior temporal lobes (vATLs) (Collins and Olson 2014). Research has shown that people have a distinct eye movement pattern, i.e., they scan faces in a particular way, when they are asked to estimate the age of unfamiliar faces (Kanan et al. 2015), and fMRI scans have shown that the FFA region of the brain is active during this process (Wiese et al. 2012). Prototypes and prototypical images held in the brain are utilized during processes of age categorization.

Although face feature changes are very gradual over time and may not seem that noticeable (to ourselves and others), humans are relatively accurate at estimating the age of others from viewing solely facial information (see Rhodes 2009). Research by Kanan et al. (2015) showed that participants were more accurate at estimating which age group a face belonged to (e.g., child, young adult, adult, and elderly) with an intraclass correlation coefficient (ICC) of 0.85, than they were at reading emotions of faces such as happy (ICC 0.75) or angry (ICC 0.65). Nkenge et al. (2008) showed 173 images of healthy Caucasian women to 48 study participants (20 men, 28 women, aged 22–64 years), who then estimated their age. On average, the participants were able to accurately estimate the age of the women just by viewing their faces, with a correlation coefficient of 0.95. However, women participants were slightly more accurate than men, who tended to perceive female faces as younger than they were. Younger participants (aged 35 and under) were more accurate than older participants (over 50 years), which could be driven by attention to different age cues. For instance, older participants' estimations were driven by lip border definition shape and eye opening size, while younger participants' estimations were driven by dark circles under eyes, smile lines (known as nasolabial folds) and the appearance of brown pigment spots on the skin (Nkenge et al. 2008). In sum, age categorization is influenced by visual processing, which can be studied via complex cognitive methods and varies depending on the age and gender of the perceiver.

Biological and Social Cues to Age

A recent review of the neuroscience of age perception revealed that the most important facial features for judging age are the size of the eyes, which become smaller with age; the size of the lips, which become thinner with age; and the evenness of skin tone, which becomes more uneven, textured, and wrinkled with age (Yarosh 2017). Skin texture and pigmentation and the greying and loss of hair are very visual clues of age, and are ones which people try to conceal and change to appear

younger, and therefore more attractive (Crary 2011). Attractiveness and perceived age are negatively correlated (Matts et al. 2007). People perceive faces with wrinkling around the eyes and mouth and uneven skin tone (e.g., presence of pigment spots) as older and less attractive, while faces of women with more even skin tone are judged to be younger and more attractive, and receive more visual attention from perceivers compared to more elderly faces (Fink et al. 2008). Perceived attractiveness is important because it underpins mate selection. Attractiveness is used to infer health and fitness of potential mates, and signals the ability to donate good genes, successfully reproduce and raise children (Halberstadt 2007; Matts et al. 2007; Perrett 2010).

For both men and women, biological and physiological changes that occur with age are mostly driven by changes in sex hormones which are highest at ages of peak fertility and then decline with age (Ferrini and Barrett-Connor 1998; Thornhill and Gangestad 2008). For instance, testosterone and estrogen build up subcutaneous bone and fat that stretches out, soften, and reduces the appearance wrinkles. Testosterone and estrogen are also responsible for thicker and darker hair for both men and women, respectively (Smith et al. 2006). Therefore, in accordance with evolutionary theory, the facial features people use to assess age are associated with sex hormones, are synonymous with perceived attractiveness, and can be used as a proxy for judging underlying reproductive potential. Indeed, physical attractiveness is significantly associated with reproductive success (Jokela 2009).

Whereas physical age cues are largely recognized consciously, for instance, people are aware of characteristics of age such as pigment spots, wrinkles, and gray hair, people also use more subtle and social cues to discern age (Perrett 2010). Social cues used to estimate age, include choice of clothes and how they fit with popular culture and fashion (Twigg 2013), tone of voice, language, and vocabulary. For example, youth culture is defined by use of certain words, invention of words or slang, and stylistic practices, such as shortening words or phrases, that are unique to teenagers (Bucholtz 2000).

The Functions of Age Categorization

Aside from informing attractiveness and mate selection, two further functions of categorization by age is that it is cognitively efficient to categorize others, but also categorizing the self can help define our social identity.

Cognitive Efficiency: Age Categorization of Others

Categorizing others into groups, including age groups, is more cognitively efficient than evaluating each person individually for two main reasons. First, it is less cognitively demanding to place individuals in a category than to determine their individual identity, especially if that person is not previously known to oneself (Cloutier et al. 2005). Second, group categorization enables us to simplify our interactions with others and infer likely characteristics of that individual based on the strong associations and meaning attached to categories. This again makes person perception more efficient (Allport 1954; Fiske and Taylor 1991; Macrae et al. 1994). For example, in first encounters, automatic age categorization may help to determine the role and relationships between individuals (e.g., mother and son as opposed to husband and wife), or may inform appropriate topics of conversation (e.g., what school they go to as opposed to buying a house). However, automatic categorization also risks oversimplification and generalization, which can lead to ageism (discussed further in the section on the risks of age categorization).

Defining Own Identity: Age Categorization of the Self

When we are old enough to categorize ourselves as belonging to an age group, it can provide meaning through both the descriptive and prescriptive attributes afforded to different age groups. Social identity theory (e.g., Abrams and Hogg 1988; Tajfel and Turner 1979; Tajfel 1981) highlights that our age and the corresponding age group we belong to or feel we belong to can help define who we are and positively distinguish us from others, both reinforcing a positive self-concept. People tend to have a repertoire of social

Categorization by Age, Fig. 1 A self-categorization model of age categorizations. The age continuum is broken up by overlapping age categories here represented

schematically. Vertical lines represent prototypical positions within subcategories

group memberships (e.g., age, gender, nationality, political affiliation, professional group), which vary in their overall importance to the self-concept. Each social identity is represented in the mind alongside attributes that describe and prescribe typical features of the group; thus, salient group memberships can inform what we should think, feel, and how we should behave.

Giles and Reid's (2005) self-categorization model of age proposed that within each age group (from teenager onward), there are prototypical positions, denoting the most typical or prototypical representations of the age group. At the most extreme positions on the age spectrum (e.g., teenager and elderly), the prototypes will be polarized slightly away from the mean, whereas for the middle categories, the prototypes will match the mean (see Fig. 1). Prototypical positions in the group are normative positions and are influential because there is social and perceptual pressure to conform to the norm of one's ingroup (Abrams and Hogg 1990). Transitioning between age groups can elicit uncertainty because one's self-concept is moving further away from one prototypical position, before moving closer to the next. According to Giles et al. (2003), uncertainty is minimized when people adapt and accept the rules and norms of the next category and redefine themselves according to the new social identity.

The extent to which age, and belonging to an age group, forms an important part of our social identity can be captured by measuring age identification, or how much people identify with a

particular age category. Separate pieces of research suggest that both the relationship between a person's chronological age and their age identification, and the relationship between self-categorized age (i.e., the age group people feel they belong to) and age identification are curvilinear. These curvilinear relationships form a "U" shape, which show that younger and older age groups have a stronger identification (belonging) with their respective age groups (Abrams et al. 2011; Fitzgerald et al. 2011; Marques et al. 2014). This suggests either that age identification is more important for younger and older age groups or that age identity is more salient for these age groups, perhaps due to transitional changes occurring around them (e.g., becoming a young adult or moving into retirement). These transitions might be particularly difficult because of the nature of physiological and social changes, which accentuate differences between the prototypical positions in one category compared to the next (teenager – young adult, older adult – elderly). Moreover, the transition into the old-age category can be particularly difficult because the prototypical representation of the group is not particularly positive and may invoke negative stereotypes and representations of old age (Garstka et al. 2004; Kite et al. 2005).

Aside from defining the self-concept, social identities are also evaluative and allow us to positively distinguish ourselves from others. Categorization of the self, and others, is the social cognitive process through which people are

assigned to social categories, making the distinction between ingroups (groups we belong to) and outgroups (groups we do not belong to; Turner 1982; Oakes et al. 1994). Therefore, a positive self-concept is maintained when belonging to a given ingroup provides a positive evaluation of oneself in relation to the outgroup or outgroups.

The Risks of Age Categorization

Despite the cognitive and social utility of being able to perceive, understand, and categorize by age, there are also negative consequences of age categorization. Early psychological research established that once categorization has occurred (whether it relates to physical objects, people, or events), two things happen; the differences between categories are enhanced, while the differences within the categories are reduced (Tajfel 1959; Tajfel and Wilkes 1963). In other words, members of different age groups will be seen as more different, while members of the same age group will be seen as more similar than they really are. This within-category assimilation or homogenization underpins stereotypes. Self-categorization theory (Turner et al. 1987) holds that our categorization systems underpin stereotyping, prejudice, and discrimination. Therefore, a consequence of age categorization is that it might lead to and perpetuate ageism; the stereotyping of and discrimination against individuals or groups on the basis of their age (Butler 1969; Abrams 2010). Research exploring the nature of age stereotypes has largely focused on those associated with older people and how they compare with stereotypes of the young (Kite et al. 2005).

The Stereotype Content Model (SCM; Fiske et al. 2002) provides a framework for exploring old-young age stereotypes, whereby older people are stereotyped as being friendlier but less competent than younger people (e.g., Abrams et al. 2009; Cuddy et al. 2005; Fiske et al. 2002). Research shows that they are also viewed as: lacking creativity, unable to learn new skills, bad drivers (Joanisse et al. 2012; Swift et al. 2013), impaired, despondent, recluse, and vulnerable

(Hummert et al. 1994), lacking adaptability, slow, less technologically savvy (Chiu et al. 2001; Magd 2003), and also grumpy and intolerant (Hummert et al. 1994; Swift et al. 2013). Alongside these negative overarching stereotypes, evidence shows that there are also positive stereotypes in which older people are viewed as polite, able to understand others' perspectives, self-motivated, productive, reliable, and dependable (Magd 2003; Swift et al. 2013; Taylor and Walker 2003).

As well as showing domain-specificity, some of this incongruence in stereotyping arises from subtyping within age groups when combined with other characteristics such as health, socioeconomic status, or social role (Brewer et al. 1981; Hummert 1990; Schmidt and Boland 1986). For example, two contrasting subgroupings of older people have been previously labeled as "golden agers" (capable, well-informed, and independent) and the "severely impaired" (incompetent, senile, and incoherent; Hummert et al. 1994). Individuals will further vary in their use of broader and more specific stereotypes depending on their own characteristics. For example, more complex representations (shown though more specific subtypes) of the older age group have been found among those closer to that age group in age (Hummert et al. 1994).

Stereotypes of both young and old contain positive and negative content, but either valence can be problematic when erroneously applied to an individual, which can result in discrimination. Age categorization may cause people to restrict what is deemed acceptable for particular age groups based on their own or others' ageist assumptions. For example, people may be judged or they may see themselves as "too young" or "too old" to pursue particular activities or roles (North and Fiske 2013). For this reason, the very act of categorizing others into different age groups and the way people define those groups has significant implications for people's choices and actions (Swift et al. 2017).

The Risks of Ageism Model (RAM; Swift et al. 2017) summarizes three pathways that ageism can negatively impact on individuals through processes of categorizing the self and others by age.

First, via stereotype embodiment, the process through which stereotypes are internalized and become self-relevant; second, via age-based stereotype threat, the perceived risk of confirming a negative age stereotype; and lastly, via age discrimination.

According to stereotype embodiment theory (Levy 2009), age stereotypes regarding the competence, health, and capacities of older people are learnt through socialization processes and then internalized during childhood and adulthood. When people get older, these stereotypes become self-relevant. They are applied to the self through the process of self-categorization, and can become self-fulfilling, resulting in negative outcomes influencing memory, cardiovascular reactivity, and longevity (Levy 2009; O'Brien and Hummert 2006).

Stereotype threat theory (Steele 2010; Steele and Aronson 1995) posits that certain situations can put older adults at risk of confirming negative age stereotypes, potentially leading to their perpetuation. A review and meta-analysis of 22 published and 10 unpublished studies (including 82 effect sizes) revealed that older adults who were placed in a situation where they faced the threat of being “judged” negatively in terms of their age subsequently underperformed on cognitive and physical tasks (Lamont et al. 2015).

Aside from the risks of self-categorization, we may also disadvantage others by categorizing them into a given age group. Research has focused on the problem of age discrimination in health and social care (Swift et al. 2016), the workplace (Walker 1993; Abrams et al. 2016), and in the media (Martin et al. 2009; White et al. 2012) in particular. The RAM highlights the unique nature of ageism and categorization by age by outlining how we are all vulnerable to negative stereotypes and representations of age. Unlike other common forms of prejudice and discrimination (e.g., sexism, racism), ageism is not based on predominantly closed and fixed social categories, instead we move through different age groups across the lifespan. The inevitability of aging means that for most people, negative age stereotypes will eventually become self-relevant.

Conclusion

In summary, the process of categorization, or classifying people, objects, or any stimuli from the world around us into groups, is a fundamental process studied by psychologists. It underpins perception, cognition, and social interaction (Tajfel and Turner 1979). While age boundaries can be fluid, prototypical representations or images we hold in our mind about members of age groups tend to impose distinctions that we use consistently for estimating others' age (Rhodes 2009; Nkenge et al. 2008). Accurate age perception provides a selective advantage for identifying potential mates. We estimate age using visual cues such as hair color, skin texture and tone, size of the eyes, lips, and appearance of wrinkles or lines. Some of these features we try to amend to deceive others of our age. Although basic cognitive processes of perceiving and estimating others' age is relatively well understood, the subjective boundaries that define age groups are less well researched. Age group boundaries seem to vary according to setting, culture, and characteristics of the person categorizing which may vary, adding levels of complexity. Categorization by age serves a social function helping to define the self, and others in relation to the self. It can help to define the self by providing a more meaningful social identity, and help to smooth social interactions with others. However, both these functions come with risks. In accordance with the RAM, self-categorization and age discrimination from others can be particularly problematic for older adults because of negative age stereotypes associated with aging and older people. Negative age stereotypes can restrict our own decisions and behaviors to those deemed “age appropriate”. Older adults can feel under threat if they are perceived or judged negatively in relation to their age, which can impair performance. Negative age stereotypes can also be used to justify unfair or discriminatory treatment.

Categorization by Sex

Kerri L. Johnson and Nicholas P. Alt
University of California – Los Angeles,
Los Angeles, CA, USA

Synonyms

[Gender categorization](#); [Sex categorization](#)

Definition

Categorization by sex refers to the cognitive and socially informed decision processes by which observers judge whether an individual is male or female.

Introduction

Sex categorization is the act by which observers sort others into one of the most predominately used social categories. From an evolutionary perspective, the capacity to determine whether someone is a male or female underlies critical socio-evaluative and behavioral decisions including reproduction (i.e., mate selection) and survival (i.e., threat detection). This entry provides a broad

overview of the theoretical models that account for sex categorization and the sensory cues that inform our sex categorization judgments. Additionally, it describes the cognitive and evolutionarily based factors that modulate and bias sex categorization decisions, and concludes with a discussion of the broad downstream implications.

Theories of Social Categorization

Based on merely a glimpse of a person, observers rapidly and with little conscious attention make inferences about whether that person is male or female (although these two categories are not exhaustive, Westbrook and Saperstein 2015). Early theoretical models reasoned that sex categorization, and social categorization more generally, equipped observers with a beneficial cognitive shortcut that reduced the inherent complexities of the social world (Allport 1954). By judging someone as male or female, observers could rely on associated knowledge structures to make inferences about that person's potential traits and behaviors (Macrae and Bodenhausen 2000). In this way, social categorization has been argued to provide an efficient, adaptable, and highly generalizable means by which observers perceive others in terms of their potential social affordances (i.e., the functional capabilities offered to the perceiver; McArthur and Baron 1983). At the same time, these generalizations based on sex category membership also have the potential to engender more nefarious outcomes such as stereotyping, prejudice, and discrimination (Macrae and Bodenhausen 2000).

Early evidence from social psychological research largely supported the claim that social categorization by sex is ubiquitous and that it occurs relatively automatically. For instance, by studying memory, researchers showed evidence that observers spontaneously extracted and used sex categories when recalling information about speakers who were engaged in a conversation. Deemed the *Who-Said-What Paradigm*, research results consistently showed that participants made more within-category errors (e.g., misattributing a comment to someone belonging to the same social

category as the original speaker) than between-category errors (e.g., misattributing a comment to someone belonging to a different social category as the original speaker). Thus, utterances of a female speaker would be misattributed to a different woman; utterances of a male speaker would be misattributed to a different man. These consistent patterns were considered to provide strong evidence that even without the use of the social category labels (here, female/male labels), participants organized their memory in terms of sex categories (Taylor et al. 1978). Neuroscience studies further bolstered claims about the primacy of sex categorization. Specifically, in as little as 200 ms after viewing a face, electroencephalogram (EEG) signals differed for male and female faces (Ito and Urland 2003). Furthermore, developmental research suggests that sex categorization emerges early in life. Infants differentiate by sex categories and show an overall preference for female faces (Ramsey et al. 2005). In general, these studies suggest that sex categorization is a ubiquitous process operating early in our development and occurring relatively automatically.

While these examinations of person perception revealed the relative ease and pervasiveness of thinking about others in categorical terms, they also conceived of social categorization as a discreet and self-evident judgment. Based on the early visual perception of another person, the individual is categorized discretely as either male or female. This relative indifference to what compels social categorization judgments aligned with some early models of person perception, which focused specifically the consequences of social categorization such as stereotyping and person-trait inference (Brewer 1988; Fiske and Neuberg 1990). Such models were mute with respect to the process by which categorizations unfold in the first place. In the early 2000s, this particular question inspired a number of social psychologists to seek a more comprehensive understanding of how sensory information compels sex categorization judgments. Exploiting paradigms that were more common in the vision and perception sciences, these researchers isolated the specific facial and body features that inform accurate sex categorization judgments (Brown

and Perrett 1993; Cutting 1978; O'Toole et al. 1998), and these insights became integrated within the more social cognitive literature. For example, Macrae and Martin (2007) found that visual features alone can facilitate social category activation (e.g., viewing only hairstyles activated sex categories) and that under restricted viewing time (25 ms), hairstyle cues could even override the importance of actual sex category in social judgments (e.g., long haired men and short haired women activated female and male sex categories, respectively).

By taking a more integrated approach, social psychologists began unpacking the decision processes that underlie sex categorization. Specifically, by identifying both the visual cues in the target of perception that compel sex categorizations, and the cognitive and motivational factors that reside within a perceiver (e.g., stereotypes), a new field called Social Vision began to take shape (Adams Jr. et al. 2011; Balci et al. 2010; Johnson and Adams 2013). Social Vision research sought to integrate perceptual and social psychological processes to reveal not just the downstream consequences of social categorization but also the earliest determinants by which social categorization occurs.

One key insight afforded by this novel perspective was that social categorization judgments are dynamic, rather than discrete as previously thought. That is, sex categorizations arise via a dynamic process that unfolds across a brief temporal time period (Freeman and Ambady 2011; Freeman et al. 2008). This process was documented using cutting-edge methodological tools such as mouse-tracking. Participants used a computer mouse to select the appropriate category label (i.e., male/female) for a set of faces, presented individually. By tracing the trajectory of each sex category judgment, researchers discovered that not all sex categorizations were equally efficient. Categorizations of more prototypical male faces (e.g., faces morphed to be 100% male), occurred in a highly efficient and direct manner compared to categorizations of less prototypical male faces (e.g., faces morphed to be 75% male and 25% female), and a similar pattern emerged for categorizations of female

faces. These results showed that social category decisions exploit visual features and reflect their variability (often referred to as bottom-up factors that originate in the target of perception). Thus, even when the ultimate category judgments yielded the same outcome, the efficiency of the decisions, as measured by mouse trajectories, was prone to vary as a function of the visible cues in the face (Freeman et al. 2008).

In addition to the impacts of variability in the target of perception, observers themselves approach social categorization tasks with their own motivations (often referred to as top-down factors that originate within the perceiver) that can impact sex categorization judgments. For example, knowledge that men are stereotypically, and in some cases demonstrably, more violent and aggressive than women (Archer 2004) might influence social categorizations. Under conditions of uncertainty, observers might be prone to make more male categorizations, thereby adopting a “better safe than sorry” heuristic (see ► “Error Management Theory”; Haselton and Buss 2000). Indeed, sex categorization of full body images that varied in waist-to-hip ratio, showed a substantial male categorization bias – the perceived boundary between male and female was significantly skewed which led observers to categorize more body shapes as males, compared to what would be expected based on population-level distributions. Furthermore, participants, who were primed to be fearful prior to providing sex categorizations, made more male categorization judgments compared to participants who were primed with more non-threat relevant emotions such as happy or sad (Johnson et al. 2012b).

Similar top-down impacts have been documented in other contexts, as well. Results from neuroscience studies revealed that participants' sex categorizations of targets who displayed cues of gender atypical job occupations (e.g., a man as a florist or a woman as a judge) corresponded to greater activation in brain areas associated with person processing (e.g., the fusiform face area, fusiform body area, and extrastriate body area) and conceptual conflict resolution (e.g., the dorsolateral prefrontal cortex; Quadflieg et al. 2011). Together, these findings

provide evidence that top-down factors that originate in the perceiver, such as motivational concerns to safety and stereotype knowledge, can affect sex categorization judgments.

Finally, the relatively newer models of person perception provided insights about how social categorization might unfold for multiple orthogonal category dimensions simultaneously (e.g., age, sex, race/ethnicity). This research has found that the coincident perception of categories such as sex and race/ethnicity renders them interdependent. For example, the race/ethnicity categories Black and Asian often are tethered to the sex categories male and female, respectively. Thus, Black individuals are more likely to be and are more easily categorized as male; Asian individuals are more likely to be and are more easily categorized as female (Johnson et al. 2012a). The reverse is also true: cues to sex category facilitate congruent race categorizations (Carpinella et al. 2015). These findings further illuminate the way bottom-up (e.g., shared facial overlap) and top-down (e.g., shared gendered stereotypes) factors influence sex categorizations, even across different social categories.

In summary, sex categorization results from the rapid integration of bottom-up perceptual processes (e.g., features and gender typicality of faces and bodies) and top-down motivational and social cognitive processes (e.g., emotions and stereotypes) that collaborate to yield a judgment. Current models characterize these judgments as a product of a probabilistic and integrative process that occurs rapidly and readily (Freeman and Ambady 2011). Next, we specify the bottom-up cues that compel sex categorization, describe how categorizations are biased by top-down influences, and discuss the impact of sex categorization for evolutionary informed processes.

Cues to Sex Categorization

Visual Cues

While multiple sensory cues inform sex categorization judgments, a vast majority of research has focused on visual cues. These cues range from

specific features such as hairstyle to full body cues such as walk motion and the body's morphology.

Face

Early work in understanding sex categorization focused on the perception of faces, and it identified the numerous features that can reliably convey sex category information. By limiting the cues that were available to observers across a series of trials, researchers could determine the relative importance of various regions of the face for making sex categorizations. Remarkably, sex categorization accuracy was highest, and was significantly above chance, when observers viewed only the eyebrows and eyes, followed closely by the jaw, chin, and mouth. The only region that led to inaccurate categorization was the nose (Brown and Perrett 1993). This sex categorization acuity grows stronger when observers view whole faces, with sex categorization accuracy nearing 100% and taking approximately 1 s of unconstrained viewing time (O'Toole et al. 1998). Other features such as skin tone can also convey sex categories reliably, with males typically having darker and rougher skin than females (Bruce et al. 1993). Additionally, the spatial distance between specific facial features differs between men and women, including the distance between the upper eyelid and brows, thus compelling accurate sex categorizations (Campbell et al. 1999). Further still, although relatively immutable, many visual cues can be intentionally accentuated or minimized in accordance with socially constructed norms. Consequently, factors such as hairstyle (Goshen-Gottstein and Ganel 2000), facial adornments (e.g., earrings), and cosmetic use (Russell 2009) can each cue and modulate sex category judgments.

Of course, in addition to specific facial features, holistic impressions of the face also influence sex categorization. The facial-width-to-height ratio (FWHR), calculated by dividing a face's width (e.g., the distance from ear to ear) by its height (e.g., the distance from the upper lip to the upper eyelid), largely differs in men and women. A meta-analysis of 32 studies found that on average, males have higher FWHRs than females, and that greater FWHR is associated

with more masculine facial ratings (Geniole et al. 2015). Importantly, evidence suggests that high FWHRs convey threat and dominance, and that there is a small positive correlation between FWHR and male's aggressive behaviors (Haselhuhn et al. 2015). However, this work is necessarily associative, thus it is not clear whether individuals with higher FWHRs *are* more aggressive and dominant or are simply viewed and treated as such. While some researchers have advanced the hypothesis that for males, greater exposure to testosterone is associated with higher FWHRs, this remains an uncertain proposition (Bird et al. 2016; Welker et al. 2016).

Bodies

Sexual dimorphism is also observed in body cues, which in turn serve as visual cues for sex categorization. While specific visual cues from the body can lead to accurate sex categorization, such as images of hands (Gaetano et al. 2014), much work has investigated the whole body in terms of its morphology, shape, and motion. Indeed, since faces require relatively close distances to be clearly seen, being able to tell sex from further away, via body cues, likely would be evolutionarily advantageous (de Gelder 2006).

In terms of body morphology and shape, visually obvious population-level differences such as height and weight (e.g., males, on average, are taller and heavier than females) cue accurate sex categorization (Gray and Wolfe 2005). Additionally, waist size and the waist-to-hip ratio (WHR) can also reliably inform sex categorizations (Lippa 2006), with males generally having higher WHRs.

The body however is not a static figure, and a body's movement can also inform sex categorization. Using point-light displays – in which video clips of white dots, placed on the body's major joints, move through space – researchers found that observers can accurately categorize sex from a variety of movement cues such as walking, throwing, and hand waving (Barclay et al. 1978; Cutting 1978; Johnson et al. 2011; Kozlowski and Cutting 1977). When judging the sex of walk motions, shoulder movements in the frontal plane (i.e., front to back shoulder rotation;

“shoulder swagger”) and hip movements within the sagittal plane (i.e., side to side hip translation; “hip sway”) compelled male and female judgments, respectively (Johnson and Tassinari 2005). Moreover, while body shape and motion have often been investigated as orthogonal cues, research that integrated both morphology and movement cues revealed that body shape takes precedence over movement for sex categorizations. While movement did cue sex, eye-tracking data revealed that visual attention was focused more on the waist (yet only when sex was unknown), as opposed to other areas of the body, suggesting the primacy of body shape for making sex categorizations (Johnson and Tassinari 2005).

Other Sensory Cues

Accurate sex categorizations can also be informed by a variety of other sensory cues. One potent auditory cue is the voice. Based on studies identifying sex differences in vocal qualities such as fundamental frequency (perceived pitch), timbre, and formant frequency, researchers exposed listeners to vocal clips of vowel segments and found high accuracy for sex category judgments (Lass et al. 1976). Interestingly, sex categorizations based on auditory perception show similar overlaps with other observations. For example, the visible differences in the walk motions of men and women also carry a reliable acoustical signature. Merely hearing footfalls provides a sufficient amount of information for listeners to make accurate sex category judgments (Li et al. 1991).

Other sensory cues have received less empirical attention but tend to show a robust pattern implying that sex categorizations might rely on other sensory modalities, as well. For instance, male and female scents provided to observers while they made sex categorizations of point-light walker displays reliably altered their perception. Heterosexual men who smelled female pheromones judged point-light walkers as more feminine; heterosexual women who smelled male pheromones judged point-light walkers as more masculine (Zhou et al. 2014). Additionally, the emotion being conveyed in a touch depends on the dyad's sex composition (Hertenstein and Keltner 2011).

Overall, multiple perceptual cues, ranging from faces to bodies, and cutting across a range of sensory modalities, provide reliable information from which observers accurately and efficiently judge sex. These cues form the evidentiary base for our sex categorizations; however, how we interpret and evaluate these cues also influences our ultimate judgments. We now consider how sex categorization judgments might be more broadly influenced.

Modulations to Sex Categorization Processes

Observers are not merely passive recipients of bottom-up sensory inputs, but rather are active participants in the social perceptual process. Thus, in addition to the sensory information available to them, observers also harness preexisting knowledge structures and personal motivations when they render a sex category judgment. These “top-down” factors that originate in the perceiver can thus modulate our responses in ways informed by evolutionary psychology. Next, we review these processes, which span a range of social cognitive and motivational phenomenon.

Social Cognitive

One consequence of social categorization is the activation of stereotypes. While early research documented the extent of stereotype activation following exposure to images from a specific social category (Macrae and Bodenhausen 2000), recent work suggests this process is bidirectional. Knowledge of stereotypes can also influence sex categorizations. For instance, stereotypes exist regarding the expression of different emotions, with men associated more with anger and women associated more with happiness (Plant et al. 2000). Because of this, the incidental perception of emotion can bias sex categorizations. When viewing ambiguous point-light-displays of body motions, observers were more likely to judge motion displays that displayed anger (i.e., a point-light hand throwing a ball in an angry manner) as men, but body motions that

displayed sadness as women (Johnson et al. 2011). Interestingly, phenotypic characteristics of the face also overlap with these sex-based emotion stereotypes, and they influence judgments. In one study, masculinizing faces lead them to be viewed as angrier, but feminizing faces lead them to be viewed as happier (Becker et al. 2007). Similarly, facial displays of emotion also impact sex categorizations (Hess et al. 2004).

Evidence also suggests that seemingly orthogonal social categories can influence judgments about one another, such as race/ethnicity impacting sex categorizations (Stroessner 1996). Because stereotypes associated with the categories Black and Asian overlap with the categories male and female, respectively, sex categorizations differ as a function of race/ethnicity. Black faces are more efficiently categorized as men, and Asian faces are more efficiently categorized as women (Johnson et al. 2012a). The reverse is also true (Carpinella et al. 2015). Thus, as perceivers, the stereotypic knowledge we bring to the categorization process can affect sex categorization.

Additionally, some judgments show systematic biases, such as what could be regarded as a persistent male categorization bias. Across a variety of stimuli, visually sex-ambiguous features such as hands, babies faces, and body shapes (e.g., bodies that occupy the mid-point between a male and female distribution) are more frequently categorized as male than female (Gaetano et al. 2014; Johnson et al. 2012b; Nagy et al. 2000). Recently evidence from our lab suggests that this male categorization bias occurs for judgments of faces, even though they tend to be less ambiguous than other classes of stimuli. One source for this influence could stem from broader associations between a “person” or “people” and males, as we often conjure images of a man when asked to simply think of a person (Silveira 1980). In these cases, devoid of any sex-based cues, male maybe the default sex category.

Motivational and Evolutionarily Informed Influences

Beyond the effects of associative knowledge, motivational concerns also impact sex categorization. For instance, to better understand potential

mechanisms underlying the male categorization bias, researchers probed how an observer's emotion state might exacerbate/attenuate biases in judgment. They found that the tendency to categorize sex-ambiguous bodies as male was more pronounced when observers were induced to feel fearful, relative to happy or sad (Johnson et al. 2012). Why might this be the case? On average, men are more physically formidable than women, and they are stereotyped as being prone to violence (Archer 2004). Particularly under conditions of uncertainty or when experiencing threat, observers appear prone to err on the side of caution, in this case rendering more male categorizations. Importantly, this pattern is consistent with biases that have been observed in other domains of judgment (Haselton and Buss 2000). These findings highlight an important role for motivational concerns in shaping sex categorization decisions.

Although more limited in scope, some evidence indicates that individual differences in perceivers can influence sex categorization judgments through adaptive person construal mechanisms. Specifically, women who are at peak conception risk (i.e., ovulation) are faster to categorize male faces and show greater facilitation for male stereotypes than women who are at low conception risk (Macrae et al. 2002). Furthermore, among men, higher relative testosterone levels were associated with slower categorization of female faces, but no difference in the categorization of male faces. While this pattern of results was unexpected given the observations for hormonal fluctuations in women's judgments, the authors argued that perhaps men paid more attention (and had longer view times) for sexually relevant faces (Johnston et al. 2011). Overall, this work suggests that sex categorization is modulated both by the sexual relevance of the target, the sex of the perceiver, and fertility.

Evaluative and Broader Implications

From an evolutionary psychology perspective, sex categorization underlies a number of domains

including mate selection and threat evaluations. We review each of these in the final section of this entry.

Mate Selection

Attraction and mate selection often go hand-in-hand, with mate selection focused on gaining the best opportunity for healthy reproduction, and attraction serving as its primary mechanism (Little et al. 2011). One cue critical to sex categorization and attraction is masculinity and femininity. As a general pattern, feminine women are deemed more attractive than masculine women (Perrett et al. 1998). Yet, this pattern is less consistent for judgments of men, with the literature providing mixed evidence about whether masculinity enhances the attractiveness of men. Studies using a variety of methods including real and morphed faces have indicated that masculine features are judged attractive (DeBruine et al. 2006; Johnston et al. 2001), while others find that more feminine features (and less dominant ones) are judged more attractive (Little et al. 2001; Perrett et al. 1998).

One possible resolution to these discrepant findings involves the trade-offs hypothesis (Gangestad and Scheyd 2005). This hypothesis is predicated on the fact that asymmetric costs to mating shift women's preferences for masculine and feminine characteristics. For instance, since facial masculinity is associated with both positive characteristics (e.g., better health outcomes) and negative characteristics, (e.g., lower perceived warmth and greater perceived dominance; Keating 1985), women are likely to differ in the weight attributed to each consideration. Indeed, several systematic shifts in preference have been documented. For instance, women prefer more masculine faces at times when they are fertile (Johnston et al. 2001; Penton-Voak and Perrett 2000) and when making judgments about a short-term mate, rather than a long-term mate (Johnston et al. 2001; Penton-Voak and Perrett 2000).

More broadly, the compatibility between a target's perceived sex (male and female) and its gender typicality (masculine and feminine) also drives attractiveness. Specifically, once the sex of

a target is determined, the degree to which the target exhibits gender-typical versus gender-atypical actions influences judgments of attractiveness. For instance, Johnson and Tassinary (2007) found that body shape provides a potent cue to sex categorization (e.g., male or female), and body motion provides a cue to gender-typicality. To the degree that these two cues aligned, that is, a body evokes a male judgment and body motion evokes a masculine judgment (or visa versa for female body morphology and feminine gait), then targets were rated as more attractive. This finding places sex categorization as a cornerstone of attractiveness, as a target's sex provides the lens from which gender typicality and attractiveness are judged.

Threat and Trait Evaluations

As described above, men and women differ on a variety of perceived traits. One well-established pattern involves sex differences in threat and hostility. Compared to women, men are rated as, stereotyped to be, and inclined to behave in more threatening and hostile manners (Archer 2004; Keating 1985). Population-level data concurs. In fact, men comprise the bulk of homicide victims, and archeological evidence finds that mass graves from Medieval time (AD 1300–1350) include more men with injuries indicative of violence and war (Boucherie et al. 2017; Kellermann and Mercy 1992). It is perhaps unsurprising, therefore, that these actuarial accounts of sex differences are mirrored in studies that probe stereotyping: men are consistently and strongly stereotyped to be more aggressive and hostile than women (Prentice and Carranza 2002). As mentioned above, these associations between men and hostility account, in part, for a range of findings described in earlier portions of this entry. These associations also have broader implications for categorizations that occur not only for faces presented in isolation but also for groups of faces or ensembles. Indeed, observers are highly sensitive to the relative ratio of men to women in multi-person arrays, and the perceived threat posed by a group increases concomitantly as the number of men increases. Put simply, male dominated groups appear to be threatening (Alt et al. 2017).

Conclusion

Here we have characterized sex categorization as a fundamental aspect of social perception. Upon merely a glimpse, observers readily and reliably exploit cues in the face and body to categorize others as either male or female. Although largely accurate, sex categorizations are prone to external influence, as well. At times, cues within the target of perception shift categorizations to favor either a male judgment (e.g., when the target is angry or Black) or female judgment (e.g., when the target is sad or Asian). At other times, observers' own feelings and motivations steer the judgment process to favor a male categorization. As such, sex categorization appears to serve pervasive and persistent evolutionary and social needs among perceivers.

Cathedral Acoustics

Lane Starratt
Atlanta, GA, USA

Synonyms

Architectural acoustics; Auditory properties of rooms; Religious building design

Definition

The designed aural qualities of large religious spaces.

Introduction

Architectural acoustic design, at its core, utilizes two fundamental properties of sound waves: reflection and absorption. The characteristics of a room that determine how sound waves are reflected and absorbed include both the materials used in construction as well as the size and shape of the room. Reverberation time is the unit of measure that identifies how sound waves respond inside a particular room. A space built with flat dense materials will generally have a long reverb time while one with rough soft materials will have a short reverb time.

Earliest Acoustic Amplifiers

There are examples of man-made structures demonstrating acoustic principles in construction of spaces used for religious services by the Mayan civilization from approximately 600 C.E. In central Mexico, there are indications that the Temples at the city of Palenque utilized different construction techniques for rooms that have different purposes. Symbols in these rooms identify different types of sound, including animal and nature sounds, the human voice, and musical instruments. One theory is that each room has been designed to amplify the type of sound the symbol identifies by utilizing different reverberation times. A modern study of these rooms shows that the voice rooms have a short reverb time that will amplify the spoken word but retain clarity, while a room with a bird symbol will have a longer reverberation time that can be used to allow a human to mimic this animal. This appears to indicate that the builders of these Temples had a basic understanding of their construction techniques' acoustical properties (Garza et al. 2008).

Renaissance Acoustics and Religious Music

Cathedrals and churches of the Renaissance period are typically large square rooms, often domed, built of marble, stone, and plaster. Vast spaces and dense materials give these rooms quite

a long reverberation time, often exceeding 10 s when the room is empty. This seems counterintuitive, though, given that the advances in musical composition of the Renaissance period were polyphonic composition (the use of multiple simultaneous melodies) and polychoral performance (the use of multiple spatially separated choirs) and that these are both impaired by long reverberation times. Advances in modern computer-assisted acoustical modeling have answered this question.

A recent survey of the Non Basilica del Santissimo Redentore in Venice, Italy identified two primary acoustical properties that worked together to reduce reverb time and improve aural clarity during musical performances. When the Redentore Basilica is empty, the room has a reverb time of approximately 7.5 s. The effect of this is that most music or spoken word in this space becomes muddy and unintelligible. However, this recent modeling of the space reproduced the Basilica as it would have appeared during the Festival of Redentore. On these festival days, the walls of the Basilica would have been covered with ornate tapestries and full of congregants, which would greatly increase the amount of sonic absorption in this space and reduced the reverberation time to 3 s. This improved the clarity of the room and would allow for a great appreciation of the ornate Renaissance musical composition.

The second acoustic property of the Basilica is that the dome of the cathedral works like a sonic reflector to focus the sound and disperse it uniformly throughout the entire space. This has a twofold effect. First, it allows each attendant at the ceremony to experience a fairly consistent musical performance regardless of their position. Second, it gives the appearance that the music is descending upon them from above with an otherworldly and encompassing quality (Boren et al. 2013).

Modern Cathedral Technology

Today, places of worship take full advantage of all the resources that developments in electronic and digital technology have provided. For example, the Lakewood Church in Houston,

Texas is a converted sports arena and can accommodate nearly 17,000 attendants. Addressing a congregation of this size would be impossible without modern amplification techniques and include problems that would have been unimaginable to the architects of previous eras.

Currently, common practice is to use the most absorptive materials and least reflective room designs to reduce the reverberation time to the smallest possible value. This will give the amplified signal the optimum amount of clarity for the spoken word. In those cases where some reverberation will enhance the quality of the music, an electronic or digital reverb device can mimic the effects of a natural reverb and can be set to the most desirable time.

Excessive reverb time is no longer the primary obstacle to audio clarity. Now, this has been replaced by feedback and phasing. Feedback is when the amplified signal from a microphone returns back into that mic and causes a loop that results in the signal increasing in volume in an out of control manner. Phasing is similar to reverberation but instead of a sound reflection off a surface it reaches two microphones at slightly different times and then both signals are amplified to a similar volume. This causes an obscuring of the original signal.

At the Lakewood Church, the pastor wears an omnidirectional lavalier microphone. This means that the microphone picks up sound from all directions and is the type of microphone that is most prone to feedback. To combat this, the location of the speakers is vital to ensure that the signal does not return to the microphone. Along with this are several Digital Signal Processors (DSP) that analyze the signal and modify it for optimum clarity and minimum feedback. To amplify the choir and their band, this church uses around 60 microphones. Forty of these are utilized for the choir themselves. In order to reduce feedback from these microphones, each member of the 200 person choir and 11 person band wears personal in-ear monitors that eliminate the need for speakers near the performers, thus significantly reducing the possibility of feedback from these sources. To reduce the instances of phasing from all of these microphones, there is an audio engineer who controls all of these sources and ensures

that only the microphones that are in use at the moment are on and that they are amplifying at an appropriate level (Emmet, 2015).

Conclusion

Throughout history, architects and engineers have sought to improve the clarity and volume of human speech. Traditionally, this pursuit has been in service of religious ceremony and creating spaces that allow for the greatest number of participants. The earliest human civilizations used simple tools to enhance the acoustic properties of natural resources and structures. As construction techniques improved in the Baroque and Renaissance eras, the acoustic properties of these cathedral spaces had a heavy influence in the compositional style and performance of religious music. Current digital and electronic technology allows for manipulation of both acoustical spaces to improve audio clarity and the audio signal to match the acoustical properties of the space.

Catherine Salmon

Vincent Barnett
London, UK

Definition

Catherine Salmon (1969–) is a leading evolutionary psychologist who is best known for her

original and engaging work on the evolutionary function of romance novels, erotic fiction, and pornography, on the evolutionary psychology of family interactions and parent-offspring conflict, on the evolutionary factors influencing body image and dieting behavior, and on the significance of birth order for understanding family relationships. She is currently Professor of Psychology in the Department of Psychology at the University of Redlands, California (USA), and has a BSc in Biology and a PhD in Psychology.

The entry will be divided into two main sections. The first main section will simply summarize the most salient content of Salmon's work as it has been presented across a range of different publications, and the second main section will engage more critically with her work and attempt to evaluate some particular aspects of it.

Erotica

In her work on the nature and function of romance novels, erotica and pornography, Salmon has convincingly argued that, because male against female human natures are profoundly different – due to sex roles in the environment of evolutionary adaptedness (EEA) being very different – the sexual psychology and consequently the sexual fantasy worlds favored by contemporary men as against contemporary women are profoundly different.

Men desire (in general) what could be termed sex-utopia (or, as has elsewhere been termed, porn-utopia), i.e., always-available, impersonal sex-on-demand from (ideally) an inexhaustible supply of beautiful, nubile women, whereas women desire what could be termed romance-utopia or relationship-utopia (Salmon 2005a, 2008), i.e., the continuous expressions of loyal commitment in a relationship with a dashing, muscular, wealthy, male hero-figure, ongoing fidelity, and frequent romantic engagements. As Salmon and Symons have explained:

We believe that genre romances are analogous to male-oriented porn in the sense that they are wish-fulfilling fantasies, well designed to pick the locks of the pleasure circuits of female brains, and largely

worthless as guides to male mating psychology or male-female relations in the real world . . . But because genre romances have been shaped in free markets by the cumulative choices of tens of hundreds of millions of women to effectively pick the locks of the pleasure circuits of women's brains, they have great power to illuminate female mating psychology. (Salmon and Symons 2010, 474)

Elsewhere, Salmon has argued that markets capitalize on preexisting (i.e., EEA evolved) preferences rather than creating new preferences by themselves, a classic example being human dietary preferences such as the evolved taste for foods that are high in sugar and fat (Salmon 2005a, 245).

Salmon's work on erotica implies more widely that the fact that men and women have evolved profoundly different sexual psychologies is a very important feature to consider when trying to understand many contemporary gender-related issues. However, because the Standard Social Science Model now employed across much of the social sciences tends to disavow such differences in sexual psychology, or at the very least to be wary of allotting them any explanatory power, the contemporary social sciences are methodologically stunted in their approach to many issues relating to sexuality and reproduction.

Family Interactions

In her novel work on family relationships and birth order, Salmon has argued that middle born children differ from first and last born children in that they generally score less on measures of family solidarity and identity, suggesting in turn that birth order influences the behavioral niche that a child will adopt from a young age (Salmon 1999). This is because first born children receive all their parents' attention for a definite period of time, as they are initially the only child in the family, and last born children often receive the same level of attention for a period, as they are usually the final child remaining in the family environment.

However, middle born children never receive all their parents' attention, as they always have competing brothers and/or sisters with whom they have to share attention and resources. Hence

Salmon argues that middle born children are more likely to be rebellious and opposed to the existing social order than first or last born children. This is due, at least in part, to the fact that they generally receive less of their parents' attention and resources than their older or younger siblings and hence are more likely to be critical of the familial social-order.

Building on the previous work of Robert Trivers, Salmon also argues that various conflicts of interest exist between parents and offspring (e.g., maternal-fetal conflict and weaning conflict), because although parents and offspring have shared genetic interests, they do not have identical genetic interests. Sibling conflict is seen by Salmon as an offshoot of parent-offspring conflict; the precise degree of sibling conflict in an individual family is affected by various intra-family factors such as birth order and birth spacing (Salmon 2005b, 522; Salmon and Shackelford 2011). Birth order and birth spacing also affect the development of individual personality traits to a degree, although very close birth spacing can reduce the impact of birth order on sibling conflict to some extent.

Body Image

On dieting, body image, and associated eating disorders such as anorexia, Salmon has argued that a concern for becoming thin by dieting may be a part of an evolved ancestral behavior that was directed to controlling the timing of human reproduction. Ancestral women who faced temporary situations that were unfavorable to childbearing could delay their reproduction by reducing their body fat in order to hinder ovulation. In the cotemporary world, the present much higher levels of female competition (and therefore higher associated stress levels) compared to the EEA could be triggering the poor reproductive environment behaviors that were part of ancestral life, such as the tendency to diet in order to lose weight (Salmon et al. 2008). Salmon is aware that this is a working hypothesis.

Elsewhere, Salmon has examined the wider role and impact of female competition for mates

and competition for status/dominance on both reproductive suppression in humans and other species, and on female behavior more generally, in order to test whether there might be behavioral mismatches between contemporary and ancestral environments in this regard. While male-male competition has been extensively studied in the existing literature, female-female competition is more subtle and elusive and therefore has proved more difficult to detect and study. In order to overcome this problem, Salmon has developed her own 20-item female-female competition stress test (FCST).

Evaluation

This final section will evaluate aspects of Salmon's work using both internal and external factors. This author is sympathetic to evolutionary psychology in general and to the aims of Salmon's work in particular but sees to a degree how individuals who might be unsympathetic to evolutionary psychology could distort aspects of Salmon's work into stereotypical forms. The terminology of "male mating psychology" against "female mating psychology" may be taken by a careless reader (either accidentally or deliberately) to mean that these two entities are entirely fixed opposites, when in reality a sliding scale operates between the "extreme female" and "extreme male" ends of a wide spectrum of nuanced sexual psychologies.

Similarly, in relation to the porn-utopia versus romance-utopia contrast (Salmon 2008; Barnett and Weedon 2014), it would be more accurate to say that there is a spectrum of human sexual fantasy universes that exist or a sliding scale that operates between the "extreme female" romance-fantasy world exemplified by Mills and Boon novels, and the "extreme male" hard-core porn-world exemplified by Pornhub's Extreme Tube. This latter point is well illustrated by the fact that today's internet porn has a large range of different styles of pornography on offer, from so-called extreme porn sex-acts such as "face fucking" and "vaginal fisting" at the very crude end of the porn spectrum, to so-called female-friendly porn,

nude-art erotica, sophisticated plot-based porn, and even comedic porn parodies at the more refined end of the spectrum.

It is evident that porn-utopia now has multiple diverse identities and also increasing female directorial participation. In fact the same is actually true of romance-utopia, which now has a very soft Mills and Boon end of the spectrum and a very racy *Fifty Shades of Grey* end of the spectrum, the latter including some sex-acts that were previously encountered only in porn-utopia.

In addition, the question of whether markets simply follow or can create taste and purchasing preferences can be seen as more complicated than Salmon appears to suggest. A more nuanced formulation would be that markets/advertising can shape consumer purchasing preferences to a degree but only within the boundaries that have been set by the preexisting cognitive architecture of the mind. For example, humans certainly do have evolved taste preferences for sugar and fat but not for the precise form in which they are presented. Therefore, markets/advertising can affect what type of chocolate bar an individual chooses to purchase (*Snickers* rather than *Mars*), but no amount of advertising could make an individual prefer the taste of dry grass to that of chocolate.

In terms of her teaching, Salmon has an overall grade of 3.6/5 at the "Rate my Professor" website – a very good score – including rankings from four students who describe her lectures very favorably (or as "awesome," with individual ratings of 4/5 or 5/5) but also including rankings from two students who describe them very negatively (or as "terrible," with ratings of 1/5). However, on further investigation into the negative comments, the 1/5 evaluations are at least partly linked to the perceived high content-level of Salmon's lectures, rather than the teaching.

Consequently, there is a consensus amongst many of the students that Salmon's lectures are at the "more difficult" end of the understanding spectrum, with a number of students reporting that her lectures are also passionately delivered and often sexuality based, which is unsurprising given the themes of her work. Extrapolating from these very different evaluations, Salmon is

(on this evidence) an inspiring teacher of bright and gifted students but perhaps a rather daunting one to some less able students.

Conclusion

Some of Salmon's research can be described as an original continuation of the themes of Donald Symons' pioneering work on sexual psychology (e.g., the romance/pornography comparison), whereas other aspects of her work (e.g., on family interactions) are creative extensions of Robert Trivers work on the evolutionary biology of family relationships. It is, therefore, not accidental that Salmon has cooperated with Symons on a number of occasions. Symons is one of the originators of contemporary evolutionary psychology and the author of *The Evolution of Human Sexuality* (Symons 1979), a pioneering account of the different psychologies of men and women. Salmon and Symons have cooperated on romance fiction (Salmon and Symons 2001, 2010) and on human sexuality more widely (Symons et al. 1996).

Perhaps one significant key to Salmon's success across such a diverse range of topics is the breadth of her understanding across the two currently separate fields of biology and psychology, providing very good evidence for the need for both depth and breadth of knowledge as a platform for conducting successful original research in evolutionary psychology and elsewhere.

Causal Attributions

Sujita Kumar Kar

Department of Psychiatry, King George's Medical University, Lucknow, UP, India

Synonyms

Etiological attributes

Definition

The attributes that explain the association of cause with effect.

Introduction

Since time immemorial, the quest of human is to know the cause of everything. To know the “cause,” human explore, observe, experience, imagine, and believe certain things. These processes help human getting closure to the understanding about “cause.” The Cambridge English Dictionary defines *cause* as “the reason why something, especially something bad, happens” (Dictionary 2015). “Cause” is always discussed in relation to “effect.” The link that is perceived to be connecting the cause with effect is known as “attribution.” Attribution refers to “the act of saying or thinking that something is the result or work of a particular person or thing” (Dictionary 2015).

Epidemiology attempts to understand the causes associated with good health and illness (Scheutz and Poulsen 1999). There are a lot of variations (across the cultures as well as among individuals of a particular culture or geographic region) in terms of their attributions to cause(s) of good health or illness. It is always difficult to establish or find out the exact cause of an effect (health-related event), though there may be many attributions explaining the association. The

attributions are usually constructed by the experiences related to the event.

Evidences are usually build by seeing the association between causes and health-related outcomes (presence of causal factor in association with illness and elimination of the causal factor resulting in recovery or remission from illness) (Scheutz and Poulsen 1999).

Causal Attributions: Types

One cause can be attributable to multiple effects and the vice versa is equally true. For example, stress can cause multiple health-related effects like depression, anxiety disorders, substance use disorder, somatoform disorder, obesity, coronary artery disease, and diabetes; on the other way around, any of the abovementioned disorders can be attributed by multiple causes (e.g., depression can be caused by stress, genetic factors, brain damage, substance abuse, endocrinal disorders).

On the basis of above associations between cause and effect, the relationship can be one to one (Fig. 1b), one to many (Fig. 1a), as well as many to one (Fig. 1c).

Causal Attributions, Fig. 1 Possible associations between cause and effect: (a) one cause to many effects; (b) one cause to one effect; (c) many causes to one effect

The “health-related event” can have multiple causal attributes, which can be biological, psychological, social, cultural, financial, as well as spiritual. The amount of attributions to the abovementioned causal domains varies from individual to individuals. The biopsychosocial model can be attributed to the causality of various psychiatric disorders.

Attribution styles play an important role in explaining the causal attributions. The attributional styles are soft psychological constructs that describe how an event (effect) is attributed to various factors. It can be broadly external (external situation or external person) attributional bias or personal (self) attributional bias (Mehta et al. 2011).

Evolution of Causal Attributions

Kelley (1973) had proposed the “attribution theory,” which elucidates that how people synthesize explanations about a cause leading to an effect (Kelley 1973). This theory basically deals with social perception and explains causal attributes of human behavior. Temporal association of cause with an event is an important determining factor of causal attribution (Young 1995). Since ancient times, it was seen that when the cause of a particular event (e.g., illness) was not known, people tend to attribute the cause to supernatural powers. For example, for centuries together, epilepsy, cholera, leprosy, chicken pox, measles, mental illnesses, and many more health conditions were perceived to be resultant of any supernatural power; hence, the remedial measures were targeted to satisfy the God or evil spirit that were believed to cause the illness (Corrigan et al. 2001; de Boer 2010; Kazeem and Adegun 2011; Lukoff and Everest 1985). However, with time the understandings about the causes of the events have evolved. Meticulous observations and research helped people understanding about the causes of illness as a result of which the causal attributions to illness as well as wellness have changed over time.

Clinical Relevance of Causal Attributions

If the health-related events are taken into account, then the effect (outcome) can be either *illness* or *wellness*. There are various causal attributions to explain illness (what causes are responsible for development of illness?) or wellness (what causes are responsible for maintaining wellness?). Understanding the causal attributions helps in generating an explanation about illness and wellness which has significant role in providing health education. For example, poor hand hygiene attributes to development of infectious disorders like gastroenteritis; so, the health education in patients with gastroenteritis focuses about maintaining hygiene. Similarly, unprotected sexual relationship may lead to development of sexually transmitted diseases (STDs), and for successful prevention of STDs, health education focuses on safe sexual practices.

Causal attributions likely influence the pathways of care as well as help-seeking behavior. For example, patients with panic disorder often attribute their symptoms to cardiac illness and first consult cardiologists or general physicians. Although panic disorder is a psychiatric disorder, the typical phenomenology (choking sensation, palpitation, tachycardia, perspiration) often direct the attribution to physical causes. Similarly, trans (possession) episodes of dissociative disorder and auditory hallucinations of schizophrenia are often referred to supernatural power and many people seek traditional healers for its remedy. The adherence to treatment for a particular illness depends on the individual’s causal attribution for his or her illness. The individuals who attribute the symptoms of illness to a medical cause seem to be more likely to be adherent to treatment than those who attribute it to supernatural powers.

Attribution to events in normal day-to-day life usually follows a pattern. Evidences support that most people attribute the cause of success and positive events to self, whereas the causes of negative events and failures are often attributed to external factors (e.g., people, situations). This is a form of bias that operates subconsciously and often referred to as self-serving bias or attributional bias (Mezulis et al. 2004).

Cognitive distortions often lead to misattribution to cause and are often dysfunctional in nature (Bowins 2004). Cognitive distortions are commonly seen in psychiatric disorders. For example, *catastrophization* is a form of cognitive distortion commonly seen in panic disorder. The patients often misinterpret their symptoms and attribute them to a severe or devastating cause (attributing palpitation to impending myocardial infarction). The psychological interventions like cognitive behavior therapy (CBT) and cognitive therapy target the cognitive distortions as resultant erroneous causal attributions are corrected (Sadock and Ruiz 2015).

Various psychological defense mechanisms are too responsible of erroneous causal attributions. For example, defense mechanisms like rationalization and projection are commonly used by individuals with substance use disorder, where the unacceptable feelings associated with alcohol use are nullified by misdirected causal attributions (Sadock and Ruiz 2015).

After an unexpected negative event, the attribution of people to the cause of the event may become negative. Evidences support that self-blaming and blaming others for the event are associated with poor outcomes (Hall et al. 2003).

Conclusion

Causal attributions are often colored by the education, awareness, belief systems, and personal experiences of the individual. Certainty of cause can be established through evidences. Investigations many a times found to be highly useful in correcting the wrong attributions to cause(s). However, majority of the psychiatric diagnosis are made clinically and seldom on the basis of investigation(s). The changes in the body structure and function could not be always demonstrable by means of investigation; hence, the wrong attributions to causes in psychiatric illnesses could not be corrected, relying exclusively on the investigations. Therefore, there is a need to address stigma, create awareness, and properly psychoeducate people suffering from psychiatric illness to correct wrong causal attributions. In the

context of health, it is utmost important for a clinician to understand the causal attributions of the client and actively address them during the treatment for a better outcome.

Causal Cognition

► Confounding Use of Tools on Physical Tasks

interesting, but contemporary theory is not ready for at least some of them. Thus, for the present, definition of causal reasoning remains tied to the terms of the relevant theories.

Causal Inferences

► Causal Reasoning in Rats (Blaisdell et al. 2006)

Introduction

An ability to decipher and act in accordance with the causal structure an animal encounters in a complex and varying world has clear value. A primary difficulty is that cause and effect in the world is opaque. Although animals are continuously bombarded with information about how events covary, covariation is an imperfect indicator of causation. Even with strong evidence that two events concur, there are many ways they may be related causally. That they reliably concur is evidence of a causal relation, but gives no more evidence that the one causes the other, than the converse; they may as well both be effects of a common cause or effects of effects of effects with common causes and so forth. Information about how events covary is not sufficient to decide among the possible causal relations that may exist among events, nor is it sufficient to differentiate between veridical causal relations and spurious concurrences. Human causal reasoners make causal attributions on minimal information, often on much less data than would be required of a statistician's calculations to reach similar degrees of confidence. Attribution of causality typically involves going beyond the data provided to form an interpretation of the underlying causal relations.

Three distinctions in causal cognition research are important to recognize. All three concern a conflation that has produced confusion in the past and a source of conflict when they have been cast as theoretical alternatives. Combining awareness of these distinctions with openness to what each component provides yields an opportunity to understand causal cognition from complementary research directions.

Causal learning/causal reasoning
 Descriptive/normative approaches
 Algorithmic/computational approaches

Causal Reasoning

Robert Ian Bowers
 School of Psychology, University of Minho,
 Gualtar, Portugal

Definition

Causal reasoning refers to all cognition about cause and effect, except learning. "Reasoning" can refer to any post-learning cognitive processing, and the qualifier "causal" stipulates concern with cause and effect. Theories of causal reasoning may concern the structure of associations, how agents use such structures, or how that structure affects action. Although focus is most often on acquired structures, this is not a principled limitation. At least some causal reasoning research with nonhuman animals is phrased in terms of dispositions.

The topic applied to nonhuman animals is controversial. The controversy is largely due to misapprehensions about the term, but there are genuine theoretical disagreements regarding even the presence of causal reasoning as well.

"Reasoning" is a connotatively rich word, and this richness can mislead by appearing to attribute more than what a theory actually concerns. This danger can be alleviated (and some of the less productive controversies avoided) by remaining faithful to the terms of a given theory and remembering not to conflate this with the richer breadth of meaning typical of dictionary definitions. All of the connotations of "reasoning" may be

Causal Reasoning Versus Causal Learning

Causal reasoning (reasoning about cause-effect relations) is appropriately dissociated from causal learning (learning about cause-effect relations). Learning is concerned with a bottom-up analysis; reasoning, top-down. Although knowledge about how causal learning occurs bears on the study of the ultimate structure, and knowledge about this structure bears on study of the way it is acquired, and integrative research that combines analyses of causal reasoning with learning carry potential worth, their distinction should be born in mind. In particular, a theory of causal reasoning may be silent on learning, or vice versa, and so caution is warranted in drawing conclusions about one in the context of theory about the other.

Descriptive Versus Normative Approaches

Much of contemporary cognitive science employs normative theories of cognition, drawing predictions about human cognition from models of how a rational agent ought to perform analogous tasks. Such approaches are fundamentally unlike older trends in psychology, which have been predominantly descriptive. The latter includes the associative learning tradition, in particular, the “laws of learning” kind of theory, which attempts to provide functions describing the relationships between sensory input and behavioral output. Although there has been resistance to normative approaches in psychology, there has been increasing recognition that the two approaches can be complementary.

Normative approaches are prevalent in ecology and economics and so in ecological and economic approaches to cognition, such as ecological rationality, behavioral ecology, and optimal foraging theory. Natural selection provides an obvious basis for normativity in natural systems, although principled evolutionary approaches of causal cognition have yet to be developed.

Normative approaches to causal cognition are relatively new, largely an addition of the 1990s. However, theory about causality itself, a topic of importance to all the sciences, is mature, such that causal cognition researchers have inherited a fully developed body of theory to lie at the basis of their theories of causal cognition. This clarity about

how causality ought to be treated is essential for approaches that rely on it as a normative basis. Knowing how a rational agent is expected to reason about cause and effect is a potentially helpful starting point in investigating how causal cognition manifests in real animals. If cognition about cause and effect is expected to serve its possessor well, rational or optimal solutions provide a null hypothesis against which to compare natural manifestations. Normative theories make prescriptions of causal cognition which can be tested.

Normative approaches solve a major problem of descriptive causal cognition research in providing independent theoretical terms for approaching questions about cognition. This fills a gap otherwise left to reliance on anthropomorphic intuitions. It remains tempting, in practice, to encumber such theories with anthropomorphic assumptions, but a normative framing does not require it, in principle.

An early objection to normative approaches to nonhuman causal cognition notes that humans tend not to abide norms of causal reasoning and even find explicit training in such norms difficult. If even humans fail to be rational, one might argue, expectations for nonhumans to reason rationally must be low. However, human irrationality bears little on the validity of normative approaches in nonhuman animals.

Normative theories of causal reasoning make predictions about patterns of behavior that serve the animal well in the face of problems with particular structure associated with cause and effect but not about how such patterns are achieved. A normative theory makes predictions without requiring assumptions about psychological manifestation. It remains necessary to specify how the terms of the theory correspond to variables in a given experiment.

Levels of Analysis: Algorithmic Versus Computational

Like in much of psychology and cognitive science, research and theory of causal cognition exist on at least two different levels of analysis, and it is not always made explicit which level is in focus. David Marr (1982) dissociated three levels of description: implementational, algorithmic, and computational. The “implementational” level describes on the

level of physiology, the workings of neurons and muscles. The uppermost “computational” level can be thought of as a folk psychological level. It is the level dealing with goals and at which selection pressures can be identified, and so is sometimes referred to the “biological” level. The intermediate “algorithmic” or “process” level concerns how the thing operates rather than what it achieves. This is sometimes described as a “psychological” level. Normative models tend to exist on the computational level, although there is descriptive research on both algorithmic (e.g., associative) and computational (e.g., tool use research) levels.

A computational-level analysis brings insights into the goals a behavior or cognitive process is meeting, and the selection pressures it is affecting, and so the functional significance of that form. It does not specify a mechanism, cognitive or otherwise. The analysis of the animal’s behavior can therefore be rational without the animal’s cognitive apparatus abiding those same rational norms.

Associative models are most often exclusively algorithmic. Computational-level and implementational-level analyses were explicitly eschewed in behaviorist psychology. Although the resistance was justified, it was overstated. Recognition of the serious limitations of exclusively computational-level research, and that it is fundamentally unlike behaviorist approaches, were important milestones. Adding recognition that computational-level analyses also have merit, in addition to their limitations, and that the two kinds of analysis are complementary, however, is just as important. By failing to specify a corresponding computational-level analysis, an exclusively algorithmic approach attempts to describe how a cognitive process unfolds without commitment to function. Attempts to present analyses on different levels as direct competitors are misguided. By combining analyses on multiple levels, each level informs and constrains theory.

Descriptive Approaches in Causal Reasoning Research

A large part of causal cognition research in non-humans is primarily descriptive, where cues

indicating some aspect of causality are manipulated and responding is measured. One can present animals with novel problems and apparatus with identifiable causal properties. Such research has largely been presented as tests of the capacity of a focal species to reason about cause and effect. If the animal responds preferentially to causal over noncausal features, it is often taken as evidence of understanding of the relevant causes and effects. The framing of such research has typically been explicitly or implicitly anthropomorphic and otherwise largely atheoretical.

Naïve Theory Theories and Causal Power

One common approach is to phrase the question in terms of whether the animal possesses a kind of implicit belief system or theory of involved causal forces. Seeing a rooster perched on a post and then hearing its distinctive call lead to the ready judgment that the rooster caused the crow. However, there is more behind the attribution than the one event following the other: had the rooster barked, oinked, or mooed, the same attribution might not be made. Causal decisions are made not only on the basis of the qualities of the present instance but also a set of expectations about what has the power to cause what.

Michotte (1946) identified several qualities of stimuli that lead people to reliably make causal attributions to explain events that are not in fact causally related. In general, things are regarded as causally related when their movements correspond – stimuli that move in the same direction or at the same rate. For example, people very readily see the movements of balls striking each other on a billiards table as causally related. When Michotte (1946) projected animated images of one shape moving up to another and stopping, and the other then taking up the same tack, people interpreted this as the first pushing the second. If contiguity was broken, and there was a delay, the illusion of causality was disrupted. This has been taken as evidence for the suggestion that we begin with a naïve physics to help us abide the world. As the example of the mooing rooster shows, it is not just physical theories upon which attributions of causality are made but theories about the causal powers of agents as well.

Tool Use

Many animals use objects in their environment as foraging aids, for example, stones to crack nuts. A few species of passerines and primates are more sophisticated and regular in their use of tools. The woodpecker finch, for instance, uses twigs to root prey out of tree trunks (Tebbich and Bshary 2004), and Egyptian vultures have been observed dropping rocks on ostrich eggs (Hunt et al. 2006). Among the several motives for studying tool use is the manipulation of causal factors in order to study causal cognition.

A number of methods have emerged that take the approach in focus: subject animals to causal problems and measure their ability to solve them. A novel apparatus with a causally relevant, but apparent, twist is presented to the animal. Is the task solved outright? If not, does performance improve with experience? And if so, does the lesson transfer to tasks that differ on a number of variables, some relevant to the problem, some irrelevant? If the animal changes strategy to solve relevant alterations, but looks past irrelevant ones, they are deemed to have demonstrated understanding of the causality underlying the apparatus.

Trap Tube-Trap Table Contraptions

The “trap tube” is a device used to test whether, when given a causally transparent problem, animals will make use of cues that are relevant to achieving the goal. It is a transparent tube with a morsel of food (e.g., a peanut) placed in the center, just out of reach. The only way to get the food is to probe the tube with a stick, which is provided. But there is a trick: to one side of the food is a depression, into which the food will fall, and thereafter be unattainable, if pushed in the wrong direction. The “trap table” presents an analogous problem, but on a flat surface, likewise interrupted on one side by a hole. Will the animal attend such traps and pull (or push) the food out the safe way?

Members of several species have succeeded at some variant of the trap tube or trap table problem, including several primates and a few passerines: capuchin monkeys, vervet monkeys, hoolock gibbons, common chimpanzees, bonobo chimpanzees, gorillas, orangutans, human children,

human adults, woodpecker finches, rooks, New Caledonian crows, and cats. Members of each of these species came to succeed in solving the task, given practice. However performance has been mixed. Individual differences were generally large, with many individuals never succeeding and those who did usually required considerable practice. Only humans have been shown to regularly avoid the trap from the start without training (Silva et al. 2005).

The conclusions that can be drawn from success or failure at the initial trap tube, however, are limited, and much of the focus of the discussions regarding what these results mean has concerned performance on transfer tasks. Once the subject has solved the trap tube, it is tested on other apparatus that are either functionally equivalent but superficially dissimilar (e.g., transfer from trap tube to trap table) or perceptually similar but with the trap no longer functional (e.g., inverting the initial tube). Varying perceptual features of the apparatus and causally relevant features independently allow one to ascertain the kinds of cues these animals attend to when solving the problem. Rooks (Seed et al. 2006) and New Caledonian crows (Taylor et al. 2009) have readily transferred to perceptually dissimilar but functionally equivalent tasks.

The other sort of transfer task, those varying function but not form, asks whether the animal persists in avoiding the trap, even though it is no longer functional, commonly by inverting the tube. That subjects of a number of species do persist in avoiding the nonfunctional trap has been taken as evidence that such animals lack understanding of how the apparatus operates. Rather, they are assumed to have learnt by trial and error to rely on cues that are functionally irrelevant to solving the problem. Capuchin monkeys, chimpanzees, and humans all show this kind of persistence with such manipulations. There are faults with the inverted trap tube control. Notably, failure to discriminate sides is poor as a test of understanding, as the same is predicted if the animal were to treat the inverted tube as a wholly separate problem. Silva et al. (2005) subjected the trap tube and trap table tasks to humans, who were able to confirm understanding of the apparatus

and solved the task without error from the first trial. These subjects nevertheless showed the same sorts of behavioral biases on the transfer tasks seen in other species, biases that had been taken as evidence against use of sophisticated cognition, notably as evidence for a wide separation of human causal cognition from that employed by other animals. This undermines interpretations of such results as failures of understanding.

Tool Selection

Do animals select the right tool for the task? If the animal understands the causality in solving a problem that requires a tool, it should be selective about the tools it attempts to use, to select a tool appropriate to function, or perhaps modify it to suit the problem. Visalberghi et al. (1995) presented capuchin monkeys, chimpanzees, bonobos, and an orangutan with a tube with food in the middle. This was much like the trap tubes described above, but without the trap. The trick was in the tools provided. Initially they were given a single functional dowel with which they could access the food. Then they were given not a single stick, but a bundle of four, which were together too big to insert in the tube. Apes opened the bundle to use a single stick to solve the task from the start. The monkeys also came to this solution, but often first tried to use the too-big bundle as it was, ineffectively. In another condition, subjects were given an assembly of dowels in an H shape, which the monkeys persisted to attempt to insert directly, whereas the apes soon learnt to disassemble it first. The readiness with which the apes modified the tool, in contrast with the monkey's persistence, moved Visalberghi et al. (1995) to conclude that these results indicate a qualitative gap in reasoning prowess between apes and monkeys.

New Caledonian crows regularly make skewers from plant material to pull insect prey out of logs. Hunt et al. (2006) presented two such birds, in their natural habitat, with vertical holes of different depths cut in the top of a log and baited with larvae, and recorded the tools made or selected and how they were used. The crows did not initially take or make longer tools in response

to deeper holes (15 cm) and so often failed on the first attempt with these. However, the second tool collected for a deeply stashed larva was regularly longer than the first. Also, when a shallow hole required a second tool, these were shorter than the second tool collected for the deeper holes. Another tool using species, woodpecker finches subjected to an analogous laboratory study likewise did not appear to pick tools to match depth of the goal object from the first trial but tended to choose larger sticks for the second try (Tebich and Bshary 2004).

Ecology and Tool Use

Species of animals vary in use or creation of tools in the wild. While most animals show no propensity to use or make tools when left to their own devices, some do. Notably chimpanzees fashion probes from plant material to extract termites from mounds and sturdier probes to spear small primate prey hiding in tree hollows, whereas other apes show no tool use in the wild. Considering the differences among these species in use of tools in nature, it is striking that no clear species differences have been documented among great apes on performance in contrived tool use tasks. Likewise, the prolific tool user, New Caledonian crow, did not outperform rooks, another corvid but one not known for tool use (Seed et al. 2006; Taylor et al. 2009).

General Criticisms of Current Causal Cognition Research

Descriptive research on causal cognition in non-humans suffers foremost from lack of theory. This produces problems of interpretation. Focus is often on collecting evidence of cognitive sophistication in a given species, to the exclusion of any deeper understanding of that sophistication, a trend that has been rightly disparaged as "trophy hunting" (Allen 2014). Success on a task is often interpreted as evidence for the animals' understanding of the underlying causality in problem, and failures are often interpreted as failures of understanding. The problem with such terms is that it is not accompanied by cogent theory. Once the animal behaves appropriately in response to a task, or fails, this approach is out of positive

predictions. Such studies appear to be engaged in providing ammunition for popular debates rather than furthering understanding.

This is not to say that such research provides no relevant data. Transfer tests in tool use studies, for instance, do appear to provide a method for ascertaining whether the animal is using cues that are relevant to the problem, which in such cases are cues indicating function. Results indicating that corvids, at least, appear to pass such tests motivate development of theory of causal understanding. Critically, however, such results do not entail such theory.

One troubling yet widespread trend in this literature is to approach causal cognition as a dichotomy consisting of mindless association versus abstract mental modeling and present these as competing and exhaustive alternatives. Experiments are commonly phrased as tests to exclude interpretation in terms of associative learning, as a path to demonstrating causal reasoning. If results permit interpretation in terms of associative learning, it is dismissed as a failure and that is the end of the analysis. This involves simplistic, archaic interpretations of associative learning (Rescorla's 1988, lament remains current), ascribing answers to metaphysical questions that entire generations of mainstream learning researchers explicitly and adamantly eschewed. Advantages of bringing the tools of learning research into the service of analyses of how animals are solving these problems have been demonstrated (e.g., Beckers et al. 2006; Polack et al. 2013). Consistency with theories of associative learning may be regarded as a strength, rather than as a criterion for exclusion.

Another apparent source of confusion involves distortions of what successes demonstrate, encumbering them with attributions of mentality not warranted by the data. The interesting set of questions concerning intentionality or propositional representations are not addressed by such methods. The precise scope of such research remains unarticulated. Solutions to this and the above problems await developments of theory.

Particularly in studies with apes, sample sizes are often tiny, and the subjects are often very experienced, sometimes with the same paradigm, and the same individuals often feature in multiple

related studies. Furthermore, among studies that involve transfer, since many of the already few subjects never solve the basic task, quite few animals have been subjected to transfer tasks, meaning that conclusions have been drawn on very small numbers.

Graphical Models

Graphical models are representations of relevance structures. Network diagrams are used to model relevance relations (the edges) among a set of focal variables (the nodes). This includes causal relevance, and so graphical models can be used to model causal relationships. This has been extended to model *reasoning* about causal relationships as well as *learning* about causal relationships. Pearl (2000) and Danks (2014) provide good introductions.

Graphical models are described both in terms of their qualitative structure, and some quantitative measure of the strengths of the relationships depicted, often a probability distribution. The qualitative aspect of graphs permits the modeling of greater structural variety than exclusively quantitative analyses. Theories differ in the focus they place on these two aspects of graphs. Graphical model-based theories of learning have typically focused on the quantitative aspect; those of reasoning have stressed the qualitative aspect. A challenge that the field is currently rising to meet is to integrate these aspects in theory. There are theories, for instance, that concern the acquisition of qualitative structures from quantitative data (e.g., Wellen and Danks 2012; Fernbach and Sloman 2009).

Application of graphical models to analyses of causal reasoning in laboratory conditioning studies needs to make a number of assumptions. First, how the terms of the theory correspond to variables in the experiment needs to be specified. Typically, stimuli and responses are assumed to correspond to nodes in the network, and associations, to the edges. Second, assumptions need to be made about how hypothetical structures are acquired. One approach is to specify the learning process by which input data leads to the formation of specific

structures. Another is to impose constraints on the specific structures that can be acquired or are involved in learning. One may assume predispositions to acquire particular network structures. Some theories assume attentional constraints that restrict learning, for instance, to single event-outcome pairs (“local computations”) or to specific graphs (e.g., the “common effect” structure, as in Single-effect Learning Theory).

The network analogy is not unique to graphical model-based views. By a range of views, what the learner acquires can be described in terms of networks of associated events. However, whereas some theories rely centrally on network terminology, among theories that describe associations solely in quantitative terms, associations may each be represented separately and so be more appropriately described as a list of association strengths than as a network. Although the tenability of the list analogy has been challenged by demonstrations of retrospective revaluation, in which learning is affected by stimuli other than those that appear in the conditioning trial, the network analogy is not expressly motivated by typical associative theories. Evocation of the image of a network, therefore, does not necessarily imply that a view intends a coherent representational scheme in which associations are collectively accessible.

Directed, Acyclic Graphs

Graphical models come in many varieties, but analyses of causal cognition typically assume directed, acyclic graphs (DAGs). A graph is considered directed if edges are asymmetrical, indicating relevance in only one direction. This fits analysis of cause and effect, since causes determine effects, not vice versa. Acyclic means that there are no cycles in the network, no relations in which an effect produces its own cause, or some cause of its cause, etc. For instance, if fear causes running from a bear, and running from the bear causes fear, the resulting network will not be amenable to such an analysis. The assumption of directed (and acyclic) associations is a prominent feature that sets such analyses apart from typical associative learning analyses, by which associations are most often assumed to be undirected.

A network of associated events provides richer information if the associations retain information about the direction of associations.

Bayesian Networks

The Bayesian Networks formalism is a graphical model-based framework initially developed to aid the calculation of probabilities of interdependent events. It works well with cause and effect (Pearl 2000). If the edges represent causal relationships, it is a “causal Bayesian Networks,” although this stipulation does not alter how the network functions. As a good way to deal with causality, Bayesian Networks secondarily provides a normative theory of causal reasoning: how a rational agent ought to reason about cause and effect.

The theory is very spare. Bayesian Networks assume directed and acyclic graphs (i.e., DAG) and the Markov and Faithfulness conditions (described below). The relations it represents are abstract, on a computational level of description.

This normative theory is important to differentiate, both from the mathematical framework on which it is based and especially from substantive theories that make use of Bayesian Networks (e.g., Gopnik et al. 2004; Waldmann et al. 2006) and sometimes leave vague what is borrowed and what is added. Conflations of these very different kinds of theory require care and transparency. It is worth accentuating that this normative theory makes predictions without requiring assumptions about psychological manifestation.

Probabilities Versus Contingencies

Expectation and probability have clear relevance to each other, and graphical model-based approaches exploit this connection. When translating this intuition into studies with laboratory animals in conditioning procedures, it is common to speak of training contingencies in the same terms as probabilities. Although animal learning procedures present contingencies, not probabilities, the connection is not new. Similar intuitions have underlain advances in learning theory, such as inhibitory conditioning, and have featured in discussions regarding the appropriate control conditions in Pavlovian conditioning studies (Ward and Jenkins 1965; Rescorla 1967).

One danger of the tightness of this connection is that it tempts conflation of the training procedure with the learning it produces. This applies to associative models in general but is less of a concern for models that only deal with the quantitative aspect of associative strength. If a learner overestimates or underestimates a correlation, the affect on behavior might be minor. For inferring qualitative structure from statistical information, however, the assumption that learners extract probabilities from contingencies needs to be articulated as such and open to empirical challenge. For instance, Blaisdell et al. (2006) was criticized (Penn and Povinelli 2007) for presenting a negative correlation between stimuli while purporting to train a “common cause” structure, by which the two stimuli should be treated by the learner as conditionally independent. The concern is well taken, and analogous to earlier concerns with explicitly unpaired control conditions, which present a negative relation between stimuli, though the animal is intended to learn that they are independent (Rescorla 1967). However, the observation is overstated if the assumption that a training procedure that presents a statistical independence is either a necessary or sufficient condition for learning that two events are independent. Specific learning models differ on this point, and such models provide the appropriate context for discussions about how learners use statistical information. Note, furthermore, that a training schedule might carry much information (e.g., temporal relationships) that affects learning beyond just concerning the statistical relationships among stimuli that has received so much attention.

Markov Condition

The Markov Condition specifies that occurrence of any event in a network is independent of other nonadjacent events, given knowledge about adjacent events. For a directed network (and thus for Bayesian networks), the constraint is correspondingly more specific: an event is independent of all non-descendants, given its immediate antecedents. This provides a computational shortcut, because it means that the probability of an event occurring can be calculated without knowing most of the network. Consideration of the local causal

environment is enough. This renders a complex network of probabilities tractable. If to calculate the probability of an event one needed to determine the probabilities of all other events that impact it, even indirectly, predicting the occurrence of an event would quickly become forbidding as complexity increased, to be practically intractable with networks of even modest complexity. The Markov condition furthermore fits intuitions about cause and effect: for assessing the likelihood of a given outcome, knowing the status of a direct cause, *C*, one can ignore all of the causal factors behind *C*.

A complementary Faithfulness assumption is also often granted. The Faithfulness assumption is the converse of the Markov condition: if two nodes are independent (conditionally or otherwise), then they are not adjacent in the graph.

Common Effect and Common Cause Models

1. Events with a common effect are dependent given the effect.
2. Events with a common cause are dependent when the cause is unknown.

In a directed, acyclic graph that satisfies the Markov condition, there are two basic circumstances in which a valid inference can be drawn between nonadjacent events in a network, even while granting conditional independence among them. Two events with a common effect are dependent given knowledge that the effect has occurred. For example, buzzing is caused by mosquitoes, but it can also be caused by a recording of a mosquito (Figure 1). Hearing a mosquito’s buzz, the

Causal Reasoning, Fig. 1 Graphs of the two situations of the example described in the text. Arrows indicate the presence and direction of causality. The *leftmost* three nodes depict the “common effect” structure; the *rightmost* three nodes depict the “common cause” structure

probability of finding a mosquito in the room greatly increases, as does the probability of discovering a speaker playing recorded mosquito buzzes (which is ordinarily quite rare). The buzz requires explanation and so all potential causes of the buzz become more probable. However, once we ascertain that there is indeed a recording of mosquito buzzing playing, the sound is no longer indicative of the presence of a mosquito, and the probability of finding a mosquito in the room immediately plummets back to baseline. Thus, whenever buzzing is heard (i.e., the effect is known to have occurred), the probabilities of these two causes of hearing buzzing become dependent on each other, even though they are otherwise independent. They are alternatives: confirming one reduces the probability of the other.

Two events with a common cause become dependent when the occurrence of the cause is unknown. Mosquitoes cause more than just buzzing. They also cause itchy bumps. Since mosquitoes cause both, these two events tend to go together, such that hearing a buzz in the room means that sleeveless arms are at risk. However, once the mosquito's presence or absence is known, hearing the familiar, uneven buzz gives one no additional information about the probability of acquiring a mosquito bite.

Conditionality

Graphical model-based views model mediated associations as conditional. By the Markov condition, if two nodes in a graph are not directly connected by an edge, this means that they are independent, in principle. If they are connected indirectly, via intermediate nodes, however, there is a relationship, but the relationship is conditional on those intermediate nodes.

Conditional causal associations are diverse in form (Fig. 2). These include not only effects of a common cause (Fig. 2a), and causes of a common effect (Fig. 2b), but also causes of causes of a common effect and so forth. It also includes cases where A causes some intermediate event that in turn causes B ("causal chain"; Fig. 2c). For instance, if melting ice might produce a flood, and the flood might destroy a given dock, there is a real relationship between the melting ice

Causal Reasoning, Fig. 2 Three forms of conditional causal association: common cause (*top*); common effect (*middle*); causal chain (*bottom*). In each case, the causal relationship between A and B is conditional on the status of some causally intermediate event or set of events

and the destruction of the dock. However, one's ability to predict the latter from the former is conditional on what is known about the causally intermediate event, the flood. Once we see that a flood has occurred and its ferocity, the current well-being of the dock is no longer dependent on knowledge about what ultimately caused the flood.

Conditional independence also has a statistical definition. The probability of C is conditionally independent of A, given B, just when $P(C|A, B) = P(C|B)$ [or equivalently, when $P(A, C|B) = P(A|B)P(C|B)$]. The structural and statistical definitions are important to dissociate: the former concerns the structure of learning; the latter concerns the structure of input data, which, in Pavlovian paradigms, are specified by the procedure. They are related, however. By some views, learners will acquire a conditional association just when the statistical definition of conditional independence is satisfied (e.g., Wellen and Danks 2012).

Superficially, conditional association resembles second-order learning, which has been amply demonstrated. However, dominant approaches do not conceive of second-order associations in terms of conditionality. Rather, associative strength is viewed as passing down a chain of associations, such that the associative strength of even a second-order CS is represented in the same exclusively quantitative terms as a first-order CS. Thus, conditionality is central difference between these two general perspectives.

Despite the theoretical centrality of conditionality, it has rarely been specifically asked whether nonhuman animals learn mediated associations in a way that respects conditionality. Bowers and Timberlake (2017) exploited the prediction that, if an association is conditional, given knowledge of the immediate antecedents of an outcome, information about the antecedents of such antecedents should have no impact on expectation of the ultimate outcome. Rats were presented with CS2-CS1-food training such that the CS2-CS1 and CS1-food correlations were the same in two groups, while the CS2-food correlation differed between groups. If subjects had acquired only a conditional association via CS1, responding to CS2 should depend on the strengths of the CS2-CS1 and CS1-food associations, which should be the same in both groups. Groups differed in response to CS2, with subjects appearing to track the CS2-food correlation, suggesting that the CS2-food association was not exclusively conditional on CS1. Thus, conditionality is not ubiquitous, placing pressure on contemporary theories to specify the conditions under which an indirect association is appropriately modeled as conditional, if ever.

Direct Versus Indirect Causation

Many forms of causal relation may produce correlation. An important distinction to draw is between the case in which A causes B, and those in which correlation of A and B is due to some indirect causal relation between them. For instance, multiple effects of a common cause (or multiple causes of a common effect) will often correlate; this is a causal relationship even though neither A nor B causes the other. Likewise, there are multiple ways for A to cause B. These include not only unmediated cause-effect relationships but also the causal chain structures.

These two general kinds of association warrant different behavior. One is expected to increase actions that bring about causes of desired outcomes but not mere correlates of the same outcomes. For instance, we adjust the temperature on a thermostat, but not a thermometer, and only if red leaves cause autumn should winter faeries take to painting trees. Causes are not simply (nor

necessarily) more predictive of their outcomes than are other predictors. Rather, the difference is qualitative.

Note that the line between direct causation and causal chains becomes fuzzy when reliability is very high (approaching 1). For instance, when one flips a light switch, the action can be treated as causing the light to burn, though the actual causal factors are more complex. A chain of local causes (e.g., local movement of electrons along a circuit) can thus sometimes be treated collectively as a single event. The world would otherwise be a very difficult place to learn about. Interestingly, this weird aspect is captured unintentionally by some theories of causal cognition (e.g., Wellen and Danks 2012).

Intervention

The actor is in a privileged epistemic circumstance in which the cues to cause and effect are especially clear. One's own actions can be assumed to be original causes, whereas most other causes cannot. For instance, seeing that a given light switch is always up when a light in the adjoining room is on, and down when the light is off, one might guess that the switch controls the light. However, the movement of the switch up or down in the past will have its own causes. This matters for determining the true cause of an event. Correlation is insufficient to infer causation. However, once one flips the switch, and sees that the light follows, it takes very few trials to feel certain that the light is controlled by the switch. Intervention introduces the kind of arbitrariness and control that are at the essence of experimentation. As an experimenter controls variables and observes effects to elucidate causation, producing an outcome by one's own action may aid the active learner for the same reasons. Intervention provides a reliable cue to veridical causality that is available to be exploited by an animal interacting with its environment (Bowers 2015).

Hypothesis-Based Causal Reasoning

To some observers, talk of causal reasoning implies possession of a kind of model or theory of causal relationships. Others object that such assumptions unnecessarily encumber analyses of

causal reasoning. Although this debate is largely academic, its weight is felt in the context of intervention. The capacity of intervention to elucidate causation is thought by some to rely on already having a hypothesis to test, and deciphering effects of an event involves prior beliefs about causal relations in the world. This is a viable objection to attempts to distance analysis of intervention from commitments to a more metaphysically weighty understanding of “reason.” Note, however, that even if such structure is necessary for a learner to benefit from intervention, it may not necessarily need to be representational; such structure could, in principle, be motivational (Bowers 2015). Questions of representation are separable from questions of structure.

Diagnostic Reasoning Versus Predictive Reasoning

Most causal cognition research among non-humans focuses on predictive reasoning, from causes to effects. A presented stimulus is conceptualized as the cause, and the animal is to infer its effects. In contrast, diagnostic reasoning is from effects to causes. When one sees outcomes, and attempts to decipher the causes, they are reasoning diagnostically. In terms of directed graphical models, predictive reasoning is reasoning in the direction of the arrows, and diagnostic reasoning is reasoning against the direction of the arrows. Diagnostic problems abound. Sounds of prey moving through a leafy forest floor, for instance, will often precede appearance of the cause, and this is what a predator faces. Prey animals face a similar diagnostic problem in identifying predators from their effects. Such animals may be prepared to infer causes from effects, rather than the opposite. Call (2004) provided evidence of a small preference among apes for opaque food cups that rattle when shaken, interpreted as inference of food (cause) from the rattle (effect).

Precedence

Precedence featured prominently in David Hume’s (1748) view of the perception of cause and effect. “When many uniform instances appear, and the same object is always followed by the same event; we then begin to entertain the

notion of cause and connexion” (Hume 1748, Sect. 7). Preceding events can be taken as causes of reliably following events. This works well for the billiard balls in his example, and research on Pavlovian conditioning has generally confirmed the importance of precedence in associative learning.

Furthermore, causality itself has temporal constraints that give it direction. Causes generally precede their effects. Future events do not cause past events. However, the converse is not necessarily true. Precedence is no assurance of causation, even among cases in which there is a veridical causal association. Screech of tires does not cause the car to crash, and the cricket’s chirp does not cause the cricket to appear. Not every learning situation is like Hume’s billiard table, in which the causes and effects are all apparent. If elements are hidden, an effect may be apparent before its cause. Thus, any implied appeal to natural selection for learning about precedence as a cue to causation should not be overstated.

Among attempts to study causal reasoning in conditioning paradigms, it is commonly assumed that precedence will cue perception of causation. A prior stimulus is assumed to be perceived as a direct cause of a following stimulus (e.g., Blaisdell et al. 2006). This assumption is more intuitive than principled. Predictors are often not causes of the stimuli they predict but effects of a common cause. Among contemporary theories, few articulate a stance on how order of stimuli should impact the perceived directionality of an association. Fernbach and Sloman (2009) provide an exception, echoing Hume (1748) in attributing an important role to precedence in perception of causality.

Treating Typical Conditional Stimuli as Causes and Effects

The common assumption that tones and lights and food in typical conditioning preparations will be perceived by subjects as causes and effects warrants hesitation. The conditional stimuli in such experiments do not indeed cause their consequences, of course. Such studies rely heavily on assumptions about the factors that cue attribution of causation, which exceeds current

understanding. Note that events assumed to be treated as causes by subjects in conditioning experiments are often even intuitively awkward. For instance, the burning of a light may cause shadows or squinted eyes but lacks the causal power to produce food. This qualm is anthropomorphic, but it accentuates a remaining gap in theory concerning the specific conditions under which animals are expected to draw a causal attribution about a given pair of events.

If incorrect attributions of causality can hinder the animal as much as correct causal attributions help, we should expect an animal to be discerning about what it treats as causal. If causal attribution is prone to error, and errors are costly, animals may be better served by undirected associations, as in typical associative learning models.

Blocking, Backward Blocking, and Retrospective Revaluation

Blocking (Kamin 1969) is a Pavlovian procedure and a learning phenomenon in which an animal is first trained with one cue that predicts some significant stimulus ($A+$) and is then similarly trained with a compound of two cues, including the first ($AX+$). Tested on the second cue alone (X), such a subject will show attenuated response, relative to other subjects who did not receive the initial $A+$ training with the first cue. Learning about the second cue is said to be “blocked” by conditioning with the first. This produced a crisis in learning theory, as it stumped many theories of learning, and a new class of theory rose that stressed prediction error reduction (e.g., Rescorla and Wagner 1972). Backward blocking (i.e., $AX+$, and then $A+$, leads to reduced response to X alone) is like Kamin’s (1969) blocking procedure, except that the order in which the two trial types are presented are reversed: first subjects are trained with the compound stimulus ($AX+$) and then the element ($A+$). Again, training with the element ($A+$) leads to reduced responding to the other part of the compound stimulus (X). First observed in human causal learning, it has since been demonstrated among rats, in a Pavlovian preparation comparable to Kamin’s forward blocking (Miller and Matute 1996; this study used a “surrogate” stimulus in place of the US), and the similarities

have been taken as suggestive of homologous processing.

To causal learning models, backward blocking is as much of a prediction as is forward blocking. However, backward blocking is a difficulty for most associative learning models, including those that rose in the wake of forward blocking, which generally assume that learning only occurs among stimuli present on a given trial. Unlike forward blocking, in backward blocking conditional responding to the blocked stimulus changes retrospectively, in the absence of subsequent experience with this stimulus. This makes backward blocking among the phenomena of “retrospective revaluation,” which collectively challenge learning theories to deal with more than just the stimuli present and so tend to favor views that ascribe structure to learning. Only a few such effects have been documented.

Outcome Maximality and Outcome Additivity

Outcome maximality effects and outcome additivity effects are challenging for many learning theories. Outcome maximality occurs when an effect is at its maximum quantity or intensity. If an additional potential cause of this same effect is presented, the rational causal reasoner has no evidence to judge the adequacy of this new cue to cause the effect. However, there is evidence that this new cue does not prevent the effect. Similarly, if an effect is absent, there is no evidence regarding a cue’s power to prevent it, though there is evidence regarding the same cue’s power to generate the effect. Thus, these two circumstances differ in the possibility to ascertain generative and preventive causes. Maximality and additivity effects have been observed in causal learning among human subjects. These are effects that typical associative models do not account for.

Beckers et al. (2006) showed sensitivity to outcome maximality effects among rats in the blocking paradigm. Subjects were first presented periodically with two intensities of shock. Then, they were subjected to a blocking procedure, using shock ($A+$, $AX+$). Where the shock subsequently presented during the blocking procedure was the lower of the two intensities, blocking was observed; where it was the higher intensity, there

was no sign of blocking. Thus, outcome maximality was observed.

Outcome additivity refers to a tendency for intensities or quantities of effects to add or not. For instance, though one waiter's passing produces a glass of champagne, and a second waiter's passing produces another, rarely does the appearance of both waiters simultaneously win you two glasses or a glass twice as big. Similarly, a predator coming upon signs of two crickets may rarely be able to catch both and so stand to gain no more in finding two than had there been just one. In other cases, two signs may mean double returns. Kamin (1969) had shown that blocking did not occur when the compound stimulus (AX) was trained with a much higher shock than the elemental stimulus (A), indicating that the effects of the stimuli add. Finding the second stimulus predictive of shock, they developed the conditional response to it. If returns do not add in this way, however, similar to the maximality effect, the causal power of a second potential predictor or cause that appears in the presence of the effect cannot be readily evaluated. In this case, the rational learner should remain agnostic regarding the second cue.

Beckers et al. (2006) tested this prediction by presenting rats with evidence that outcomes did not add. They did this by training them initially with two separate predictors of low intensity shock and a compound of both these predictors together with the same intensity of shock (C+, D+, CD+). Both stimuli together produced the intensity of either alone, evidence that intensities do not add. These rats were then subjected to the blocking procedure with different cues (A+, followed by AX+). Under these circumstances, blocking did not occur, indicating sensitivity of the subjects to outcome additivity.

Substantive Psychological Theories of Causal Reasoning

Whereas some graphical model-based theories limit claims to the most abstract, computational-level terms, others concern substantive, causative representations of causal associations. Substantive theories give graphical models tangible interpretation in terms of psychological entities.

A causal reasoner is thought to possess and act upon mental models approximating the form of networks of learnt relations. Among such theories are Causal Model Theory (Waldmann et al. 2006), by which "animals have a natural tendency to translate covariations into causal-model representations" (p. 310) (see also Gopnik et al. (2004)). The empirical support for Causal Model Theory remains weak.

By such views, when an animal learns a new association, it does so by augmenting a representational model of causal relations. However, the perspective otherwise provides little guidance on learning, instead focusing on the use of ultimately formed structures. Such views have been criticized for their inability to specify how given training procedures produce hypothesized structures (Penn and Povinelli 2007), but this is to exaggerate their scope. Alignment with a theory of learning can fill such gaps (Waldmann, et al. 2008). Whether one theory of learning will suffice for all cases and whether predispositions will need to be assumed are remaining challenges.

Such views invite integration with normative theories by assuming that the hypothetical, abstract structure from which a normative theory draws its predictions reflects the structure of the mental models the animal uses to reason about cause and effect. In other words, one can assume isomorphism between the computational and algorithmic levels. Causal model representations may generally manifest the qualities of Bayesian networks, for instance. The animal, by this view, is itself naïvely Bayesian, not just the scientist's analysis. These two levels of theory may complement each other, with the normative theory bringing specific predictions about form and the substantive theory giving these forms tangible interpretation in terms of psychological entities.

Mentality

Few theories of causal reasoning say anything about mentality, in favor or against. Some views speak in terms of mental models but do not make predictions about mentality itself. Normative theories concern form. Graphical models concern form. Associative learning models concern form.

Having a theory about form does not grant a theory about how it manifests. It is not obvious that structuring information in terms of directed associations requires a fundamentally different quality of mind than structuring the same information in terms of undirected associations. Thus, the apparently widespread belief that support for a theory of causal reasoning or alternative hypotheses in an animal demands a different view of that animal's mental life may be misguided, given the current state of such theories. Though rationality and mentality are easily conflated, neither requires the other: assuming abstract thought does not motivate claims of rationality nor does rationality motivate claims of abstractness.

"Causal Reasoning-like Behavior"

It is sometimes tempting to soften talk of causal reasoning by appending "-like behavior". This temptation should be resisted. Such phrasing is pragmatically ambiguous: it may be taken to imply that *x* is not *really* reasoning or that *x* is a good candidate for reasoning. If a pattern of behavior appears to be interestingly treated like causal reasoning, it is preferable to be clear about the specific similarity meant.

Learning About Cause and Effect

Although the distinction between learning and reasoning is important to recognize, they are also very relevant to each other. Analyses of causal reasoning often involve assumptions about learning and vice versa. Especially given that learning and reasoning are addressed to different extents by different theories, and by different studies, and the distinction remains fuzzy in some discourse, it is pertinent to discuss learning in the context of reasoning.

Associative Learning

Despite the presence of rhetoric explicitly contrasting causal cognition with associative learning, and the absence of a notion of "causal" in mainstream associative learning nomenclature, the mature and prolific field of research and theory concerning Pavlovian and instrumental

conditioning has clear and direct relevance to causal cognition and may be considered its strongest leg. That events have concurred in the past is a good sign that they will continue to concur, expressly because it is a good sign that they are related causally. Animals had better not learn to associate fortuitous concurrences or irrelevant details of a learning circumstance. For instance, if a fair coin comes up heads in 10 consecutive tosses, one had better not acquire the expectation that coins will always turn up heads. Hence, when we learn from witnessing events covary, we are effectively learning about cause and effect, even though mainstream associative learning views often do not use such terms.

Theory concerning associative learning has often resisted reference to cause and effect. Although this has partly to do with causality playing no essential role in many such views, the resistance has been more adamant than justified on such grounds and may often have more to do with aversion to talk of reasoning. Many thinkers, notably Anthony Dickinson and David Shanks, have stressed the relevance of associative theory to causal learning.

Superfluity of Causal Reasoning in Associationist Thought

Historically, theories of associative learning have attempted to leave no gaps for a reasoning process to fill. Associations are assumed to be used in the way they are formed, such that they require no additional processing when acted upon. This is also assumed in some theories of causal learning (e.g., Single-Effect Learning Theory). It is a virtue of a theory of learning if it does not rest too heavily on a theory of reasoning. In a history of theories impressively meeting this demand, it has been emphasized.

One expense of this emphasis has been connections drawn with theories concerning any next steps. Under pressure to capture all of the structural complexity present with association strengths, motivation is lost to connect with theories expressly concerning structure, including theories of causal reasoning. Retaining an articulated stance on reasoning, even if minimal or null, may be useful in order to clarify grounds for

comparison with views that focus on different aspects of conditional behavior or just to keep in sight what one's theory explains and leaves unexplained, to help prevent exaggeration of explanatory depth. Ostensibly reason-free views of learning may often expect some manner of post-learning processing, for instance, for combining links when responding to second-order conditional stimuli. Pretense of completeness, whether intended or attributed by casual readers, hinders integration of views that offer insight about different aspects of causal cognition.

Causal Learning

The redundant-sounding designation of "causal learning" has been left to a newer class of theories of learning that take explicit inspiration or guidance from graphical models. Thus, although such theories are overwhelmingly focused on bottom-up processes, and typically say very little about causal reasoning, they often retain a theoretical connection with theory concerning a top-down component, such as the Bayesian Networks formalism. This marks a pertinent contrast with the staunchly descriptive approach of the older associative learning tradition, which builds up to no top-down theory.

Note that structured learning itself is not a new development. Ethologists have long held that learning is structured, although such views are typically not phrased in terms of cause and effect.

That covariation is a good sign of causation is a valuable heuristic, but the information given about how events covary is ambiguous concerning the causality involved. If combining information about covariation is how we learn about causality, part of the developing animal's problem is turning information about concurring events in the environment into a scheme of causes and effects. This requires reaching beyond the evidence given to turn poorer information into richer. This is how theories of causal learning need to reach farther than the older associative learning models, which they otherwise sometimes borrow heavily from. For instance, Power PC theory is explicitly an extension of the probabilistic contrast model (Ward and Jenkins 1965), and Local Prediction-Error Learning Theory is equally explicit about

building upon the Rescorla-Wagner model (Rescorla and Wagner 1972).

Causal learning theories have slowly but steadily joined mainstream human associative learning research, thereby enriching thinking about human learning. The analogous change in research and theory based on nonhuman animals has been slower and saltatory but still present. These are not different topics, but different scientific communities (and different species), which may have insight to gain from each other. Some specific causal learning theories include Power PC (Cheng 1997), Single-Effect Learning (Waldmann et al. 2008), and Local Prediction-Error Learning (Wellen and Danks 2012), with others reviewed in Glymour (2003). See also Fernbach and Sloman (2009).

Power PC

Cheng's (1997) Power PC theory ("causal power theory of the probabilistic contrast model") of causal induction builds upon the standard contingency model (i.e., the difference between the probability of an event given a second event and given the absence of the second event: $p(B|A) - p(B|\sim A)$; Ward and Jenkins 1965). Learners begin with a propensity to develop causal attributions, and attribute causal power to a candidate cause according to the observed contingency with the purported effect, corrected for base rate probabilities in the absence of the candidate cause. This combines the "covariation" and "power" approaches to causal induction, yielding a theory about how covariation information is integrated into hypotheses about causal power.

Concluding Remarks

Owing perhaps to the newness of the field, and its spanning several scientific communities, there is a lack of communication and mutual understanding that appears to be impeding progress. The field desperately needs a conceptual overhaul. In the meantime, open minds are especially necessary, and caution about what a given theory predicts and what questions are addressed by the available data. What is the role of questions of mental

content in the study of causal cognition? What kinds of theories compete with each other as explanatory alternatives? How and to what extent do theories of different levels constrain each other? These are issues that this burgeoning field needs to work through. It seems that the field needs to reorient and embrace that it is a field made of multiple, complementary approaches that deal with separate but overlapping aspects of the problem. The scope of each approach to causal cognition research needs to be clarified, as well as what sorts of conclusions each is able to draw and how such results bear on the other approaches.

Causal Reasoning in Rats (Blaisdell et al. 2006)

Francisco J. Silva and Kathleen M. Silva
University of Redlands, Redlands, CA, USA

Synonyms

Bayes net theory; Causal inferences; Causal-model theory

Definition

The process of identifying and understanding the relationships among causes and their effects.

Introduction

As descendants of Darwin, contemporary psychologists who study animal learning try to identify continuity in species' cognitive and problem-solving abilities. As descendants of Galileo, these same psychologists prefer to study animal

learning in laboratory environments that have been standardized to reduce unwanted behaviors and automated to facilitate the presentation of stimuli and the recording of responses. It was within these traditions that Blaisdell et al. (2006) conducted three experiments to demonstrate that rats were capable of causal reasoning, a form of thinking thought possible only by humans.

The type of reasoning studied by Blaisdell et al. is often illustrated by two analogies. The first analogy illustrates reasoning about a common cause: A change in atmospheric pressure causes simultaneous changes to a barometer and to the weather. The two effects (barometric readings and weather) have a common cause (atmospheric pressure). Someone who understands these causal relationships knows that doing something that directly changes the barometric readings will not affect the weather. More abstractly, Event **A** causes Events **B** and **C**, which are independent of each other. The second analogy illustrates reasoning about a causal chain: An increase in greenhouse gases causes an increase in the temperature of the atmosphere, which causes other climatic changes. Someone who understands these causal relationships knows that doing something that increases greenhouse gases will also increase the temperature of the atmosphere, which in turn will produce other changes to the climate. In a causal chain, Event **A** causes Event **B**, which causes Event **C**.

Common-Cause Versus Causal-Chain Training

Experiment 2a is perhaps the most widely discussed experiment of Blaisdell et al.'s study. The critical features of this experiment can be summarized as follows. During a training phase, a group of hungry rats was given several presentations of a light that was followed by a tone (i.e., Light → Tone). During a second training phase, these rats were presented with pairings of a light that was followed by access to a sucrose solution (i.e., Light → Food). Because the light was a common cause of both effects (i.e., Tone and Food), the two phases together formed common-cause training.

Another group of rats was trained similarly except that their first phase consisted of Tone → Light pairings. Their second phase also consisted of Light → Food pairings. Because the two effects (Light in the first phase and Food in the second phase) each had a direct cause (Tone in the first phase and Light in the second phase, respectively), the two phases together formed causal-chain training.

To test what the rats understood about the pairings they experienced across the two training phases, Blaisdell et al. divided each group of rats into two additional groups. For one of these groups, pressing a lever produced a tone. For the other group, the tone was presented independently of a rat's behavior. Neither the light nor the sucrose was presented during the test session. The researchers recorded how often the rats nosed in the feeder aperture during the tone. Nosing in the feeder was as a measure of the rats' expectation of food.

Predictions

Common-Cause Training. According to Blaisdell et al., causal-model theory predicts that, during testing, the rats that experienced common-cause training will nose in the feeder less during the tone when it is produced by leverpressing than when it is not. The rationale for this prediction is that when a subject's behavior (e.g., pressing a lever) causes an event (e.g., Tone), the subject should fully discount the previous cause of the event (e.g., Light). In other words, even if Event **A** caused Event **B** in the past, you should not think that **A** caused **B** if you did something that caused **B**. In contrast, response-independent presentations of the tone "should lead the rats [that experienced common-cause training] to reason that the temporally prior cause **L** was probably present (but missed), and to consequently expect that **F** should also be present; therefore, they should emit many nose pokes [during the tone]" (Blaisdell et al. 2006, p. 1021). (In Blaisdell et al., **L**, **T**, and **F** refer to the light, tone, and food, respectively.)

Causal-Chain Training. For the rats that experienced causal-chain training, the amount of nosing in the feeder during the tone (during the test) should be the same regardless of whether it was or was not produced by the animal's behavior. Why? According to Blaisdell et al., if the rats integrate the pairings Tone → Light and Light → Food into a causal chain, then they should treat the tone as the cause of the light, which in turn should be treated as a cause of the food (Leising et al. 2008). Regardless of how the tone is produced, hearing it starts a causal chain that leads the rats to expect food and thus nose in the feeder.

Common-Cause vs. Causal-Chain Training. The preceding analyses led Blaisdell et al. (2006) to predict that the amount of nosing in the feeder during response-independent presentations of the tone would be the same for rats that received common-cause and causal-chain training. This is also the same amount of nosing in the feeder that should occur during the tone when it is produced by a leverpress by the causal-chain rats. It is only the common-cause rats that should show a decrement in nosing in the feeder during the tone when it was produced by a leverpress. Figure 1 summarizes the procedure and the researchers' predictions.

Blaisdell et al.'s Results and Interpretation

The rats that received common-cause training nosed in the feeder less when the tone was produced by a leverpress. According to Blaisdell and his colleagues, these results were consistent with causal-model theory but not associative theories. Other researchers, though, have been less convinced (e.g., Penn and Povinelli 2007). There are two sources for this skepticism, one empirical and the other theoretical. Empirically, some researchers have been unable to replicate the most significant of Blaisdell et al.'s (2006) results – i.e., less nosing in the feeder during the tone when it was produced by a leverpress by the rats that received common-cause training. Theoretically, researchers have argued that some of

Causal Reasoning in Rats
(Blaisdell et al. 2006),

Fig. 1 A summary of Blaisdell et al.'s (2006, Experiment 2a) procedure and predictions. The bars on the *left side* of the graph pertain to the common-cause training; those on the *right side* of the graph to the causal-chain training

Blaisdell et al.'s key assumptions are questionable and vague and that their results are not inconsistent with associative theories.

Difficulties Replicating Results. Perhaps the most straightforward challenge to Blaisdell et al.'s results is that other researchers have been unable to replicate the theoretically vital interaction from the original study, whereby the presentation of the tone as a consequence of the rats' leverpressing interfered with nosing in the feeder only if the rats had received common-cause training (e.g., Burgess et al. 2012; Dwyer et al. 2009). Although failures to replicate a result can be due to many factors, one of the benefits of (higher level) causal reasoning is that it allows people and other animals to abstract the key features of a situation and then to respond appropriately. In other words, causal reasoning permits generalization. Responses that are controlled by the (lower level) perceptual and associative features of a task

are more likely to result in stimulus-bound or situation-specific responding. That Blaisdell et al.'s results are not readily generalizable casts doubt on whether these results were due to the rats' causal reasoning.

Questionable Assumptions and Methods. According to Blaisdell et al., the key prediction that common-cause rats will nose in the feeder less during the tone when it was produced by a leverpress than when it was not depends on the assumption that response-independent presentations of the tone elicit the thought that the light was presented but missed. Why? Because for the common-cause rats, response-independent presentations of the tone are not associated with food except through mediation by the light. For the tone to elicit an expectation of food, it must first elicit a memory of the light – i.e., the stimulus associated with food. Without this assumption, for the common-cause rats, the amount of nosing in

the feeder during the tone would be the same regardless of whether it was produced by a rat's behavior or not. The present-but-missed-light assumption requires close scrutiny (Penn and Povinelli 2007).

Another problem concerns the specifics of the common-cause and causal-chain training. In its simplest form, common-cause training consists of presenting one cause (*A*) followed by two simultaneous effects (*B* and *C*). In contrast, Blaisdell et al.'s (2006) common-cause training method consisted of two phases where the two effects never occurred simultaneously. Similarly, in its simplest form, causal-chain training consists of presenting one cause (*A*) followed by an effect (*B*) that is also the cause of another effect (*C*). But Blaisdell et al.'s causal-chain training consisted of training two separate direct-cause links and then supposing that the rats would connect these links into a causal chain. Blaisdell et al.'s methods deviate considerably from the simplest forms of common-cause and causal-chain training, thereby complicating interpretations of what subjects learned or how they might have reasoned about the training.

Consistent with Associative Theories. Blaisdell et al. concluded that their results were consistent with causal-model theory but not associative theories. Other researchers argue that Blaisdell et al.'s results are not inconsistent with associative theories (e.g., Burgess et al. 2012; Dwyer et al. 2009; Kutlu and Schmajuk 2012). According to these researchers, Blaisdell et al. (2006) neglected to coordinate, for example, stimulus generalization, latent inhibition, conditioned inhibition, protection from extinction, and overshadowing. Most significant is that carefully controlled studies have shown that Blaisdell et al.'s results can be explained by response competition between leverpressing and nosing in the feeder (see Burgess et al. 2012; Dwyer et al. 2009). More specifically, irrespective of the type of training the rats received, there was less nosing in the feeder during the tone when it was produced by a leverpress. Causal-model theory predicts that the effect of leverpressing will be restricted to the rats that received common-cause

training. Some theories of animal learning and behavior that can accommodate patterns of multiple responses may suggest otherwise (see Killeen 2014; Timberlake 2004).

In addition to competition between leverpressing and nosing in the feeder, some of Blaisdell et al.'s (2006) rats had a propensity for signal-directed behavior toward the light. For this reason, "the bulb on which L had been presented during training was removed from the experimental chamber. . . . A pilot experiment found it necessary to remove the light bulb on which L was presented during training to produce reliable responding to T after causal-chain training" (Blaisdell et al. 2006, pp. 5–6 of Supporting Online Material). The bulb was removed prior to testing for all rats. That Blaisdell et al. had to remove the light is evidence of the occurrence of response competition. That this competition was more apparent for the rats that received causal-chain training than common-cause training places a red flag next to any explanation for differences in these rats' behavior because of causal reasoning. Occam's razor compels scientists to use the simplest explanation that will suffice. Removing a part of the environment that interested one group of rats more than another group is a potentially simple explanation for any differences between these groups.

Conclusion

Although it was hailed as the first demonstration of causal reasoning in rats, the significance of Blaisdell et al.'s study is less clear today. There have been serious challenges to their assertion that associative theory cannot explain their results but causal-model theory can. At present, it is unclear whether rats understand that the manipulation of an effect cannot affect its cause, that exposure to sequential stimuli is the training of a causal link, that they treat absent but expected events as present but missed, or that these animals can integrate training in separate phases into a coherent causal model (Machado 2005; Penn and Povinelli 2007).

Definition

Cellular death pathways adopted by cells to prevent cancer progression.

Introduction

Cellular adaptation is the capacity of cells to respond to different types of stimuli and adverse environmental changes. Depending upon the reproducibility attributes of cells constituting the tissues, tissues adapt differently. If cells are not able to adapt to the adverse environmental changes, cell death occurs physiologically in the form of apoptosis or, pathologically, in the form of necrosis. In cancer incidences the intrinsic elasticity acquiesce to cells to progressively evolve functions that promote cell growth, disable cell death mechanisms, and evade immune surveillance and therapy (Hanahan and Weinberg 2000). There is a delicate balance between the regulation of cell growth and cellular metabolism. In a cancer cell, these regulatory mechanisms are disturbed in multiple ways to favor active proliferation of cancer cells. This genetic as well as physiological difference between normal and tumor cells therefore acquires vital importance for development of cancer therapeutics. The oxygen regulation is one important

mechanism in cancer development, wherein it is utilized to alter the metabolism and augment formation of new blood vessels. The Noble Prize 2019 has been unraveling the mechanisms involved in sensing and adaptation of cells to oxygen. The oxygen sensing mechanisms has been an important therapeutic target for drug development. Additionally, cells possess multiple death mechanisms that differentially impact tumor progression and the response to treatment. Thus, there is growing appreciation about interdependence between cell growth, metabolism, death pathways, and cancer.

The effect of oxygen levels on cellular metabolism and physiological function has also paved the way for promising new strategies to fight anemia, cancer, and many other diseases. The awarded mechanism for oxygen sensing has fundamental importance in physiology, for example, for our metabolism, immune response, and ability to adapt to exercise. Many pathological processes are also affected. Intensive efforts are ongoing to develop new drugs that can either inhibit or activate the oxygen-regulated machinery for treatment of anemia, cancer, and other diseases. In tumors, the oxygen-regulated machinery is utilized to stimulate blood vessel formation and reshape metabolism for effective proliferation of cancer cells. Intense ongoing efforts in academic laboratories and pharmaceutical companies are now focused on developing drugs that can interfere with different disease states by either activating or blocking the oxygen-sensing machinery.

Metabolic Changes in Cancer: Implications in Cell Death

Cancer cells have multiple alternative mechanisms, not known in normal cells, which allow them to survive under highly adverse conditions. In the 1920s, Otto Warburg illustrated the use of aerobic glycolysis for energy production by the tumor cells rather than oxidative phosphorylation (OXPHOS) despite sufficient oxygen and the lesser yield of ATP. Pyruvate is one of the important metabolic intermediates present at the

intersection between lactate production and OXPHOS. In normal cells, in the presence of oxygen, the pyruvate is directed into mitochondria to be converted into acetyl CoA by the pyruvate dehydrogenase (PDH) or into alanine by transamination. Inside the mitochondria, pyruvate is completely oxidized through the TCA cycle, feeding reductive equivalents to the electron transport chain. However, in case of absence/limited supply of oxygen, pyruvate gets converted into lactic acid by lactate dehydrogenase (LDH) in a process termed anaerobic glycolysis. In contrast, cancer cells shift their metabolism toward lactate production even in the presence of oxygen mainly via genetic modifications that stabilize the transcription factor hypoxia-inducible factor (HIF) involved in the adaptation of the cells to hypoxia, under non-hypoxic conditions and generating an adaptive response to the hypoxic microenvironment (DeBerardinis et al. 2008).

In addition to glycolysis, cancer also use glutaminolysis pathway, which generates reductive equivalents such as NADPH by replenishing the TCA cycle (DeBerardinis et al. 2008). Glutamine is a conditional amino acid in the sense that, under normal conditions, it can be synthesized in most cells. Glutamine provides energy through the TCA cycle as well as nitrogen, sulfur, and carbon skeletons for proliferating cells. Tumor cells have a mitochondrial enzyme, glutamine synthase (GLS), and are therefore able to convert glutamine into glutamate, thereby generating a large pool of glutamate. In vitro and in vivo studies have shown decreased tumor cell growth in limited GLS activity (Gao et al. 2009).

Recently, it has also been shown that metabolic requirement alone does not activate metabolic reprogramming but is also regulated by oncogenes and tumor suppressors. PI3K/Akt pathway is one of the most often deregulated pathways in tumor cells. Akt is one of the essential proteins, which leads to the increased expression and membrane localization of the glucose receptor-1 (GLUT-1) and stimulates phosphofructokinase activity. It thus causes augmented glucose uptake and increased glycolytic activity. The tumor suppressor p53, on the other hand, can shift tumor cells from glycolysis to oxidative

phosphorylation (Berkers et al. 2013). Thus, the precise characterization of the metabolic pathways in different cancer cells is a growing challenge, which might lead to the discovery of drugs that specifically target proteins or enzymes altered in tumors.

Apoptosis and Its Mechanism

Apoptosis is the cell's inherent mechanism for programmed cell death, particularly essential in long-lived mammals as it plays a critical role in development as well as homeostasis (Hassan et al. 2014). There are two different pathways that lead to apoptosis: the intrinsic and extrinsic pathways that correlate with the signal type. They are also referred to as the mitochondrial and death receptor pathways, respectively. The intracellular signals include DNA damage, growth factor deprivation, and cytokine deprivation (Zaman et al. 2014), whereas the most common extracellular signals are death-inducing signals produced by cytotoxic T cells from the immune system in response to cells that are damaged or infected (Zaman et al. 2014). The pathways converge at the executioner caspases.

With the onset of apoptosis signaling, changes begin to occur within the cell. These changes include activation of caspases which cleave cellular components required for normal cellular function such cytoskeletal and nuclear proteins. As a consequence of activation of caspase, apoptotic cells starts to shrink and undergo plasma membrane changes that signal the macrophage response (Hassan et al. 2014). Apoptosis is carried out by caspases (cysteine aspartyl-specific proteases), which are a class of cysteine proteins that cleave target proteins. There are four initiator caspases (caspase-2, caspase-8, caspase-9, caspase-10) and three executioner caspases (caspase-3, caspase-6, caspase-7). The executioner caspases cleave the target protein that eventually leads to the death of the cell. The pathways are highly regulated so that apoptosis will only occur if signaled. The intrinsic pathway, in particular, is regulated by the B-cell lymphoma-2 (BCL-2) protein family, which includes

pro-apoptotic effector proteins, pro-apoptotic BH3-only proteins, and anti-apoptotic BCL-2 proteins. The anti-apoptotic BCL-2 proteins inhibit apoptosis through the inhibition of the pro-apoptotic BCL-2 proteins, BCL-2-associated X protein (BAX), and BCL-2 homologous antagonist killer (BAK). BH3-only proteins inhibit the anti-apoptotic BCL-2 proteins (Zaman et al. 2014).

Therapeutic Strategies Against Cancer Triggering Apoptosis

In cancer cells deregulated apoptosis leads to longer cell survival and more time for the accumulation of mutations causing increased invasiveness during tumor progression, angiogenesis stimulation, deregulation of cell proliferation, and interference in differentiation (Hassan et al. 2014). The most common way of treating cancer is through regulating or probably terminating the uncontrolled growth of cancer cells. Targeting the cell's own death mechanism is strikingly effective method. Moreover, targeting apoptosis is the most successful nonsurgical treatment. As the avoidance of apoptosis is the major indication of cancer and is also nonspecific to cause or type of cancer, therefore, focusing on apoptosis for developing cancer therapeutics is most efficient for all types of cancer. Several anticancer drugs are there which target various stages in both the intrinsic and extrinsic pathways (Liu and Zhu 2017). Two characteristics strategies for therapeutic targeting are stimulation of pro-apoptotic molecules and inhibition of anti-apoptotic molecules (Hassan et al. 2014). Several studies have been done on therapeutic targets, which include ligands for death receptors (Lopez and Tait 2015), inhibitors for BCL-2 (Zaman et al. 2014), XIAP inhibition (Lopez and Tait 2015), and alkyl phospholipid analogs (APL), which act as apoptotic signals (Villa-Pulgarín, et al., 2017). Any stage in the pathways can be targeted for treatment; however, there is no indication of which target is most effective. As more apoptosis-inducing anticancer drugs are designed, the most effective targets will be determined.

Conclusion

So far, extensive work has been done to attain in-depth knowledge regarding regulation of tumor metabolism. Yet for the development of drugs that specifically target tumor-related pathways, there is a need to further understand the complex networking between oncogenic signaling pathways and tumor metabolism. Metabolic reprogramming might render cancer cells highly dependent on specific enzymes or processes that could be exploited for inducing cell death. However, due to multiple options of compensatory mechanisms available to tumor cells, the search for relevant targets becomes complicated process. It is essential to understand that there is no single tumor specific metabolism, rather, several programs that differ from tumor to tumor and are adjusted to the special requirements of different tumors in different tissues. The complexity of the tumor metabolism furthermore demands in vivo models to study the effect of drugs on a whole organism. Also, still there remain some puzzling and troubling questions such as whether these treatment strategies induce resistance in tumors and whether they will cause normal cells to die in massive numbers that still remain unanswered. As a result, there is an urgent need of evidence-based long-term follow-ups on patients receiving these new cancer treatments, and the current research should focus on those strategies that can selectively induce apoptosis in malignant cells and not the normal ones.

Definition

Data collected about an entire population, usually by national governments, to assist with state functions. When accessible by researchers, these large databases can be used to evaluate theories of human behavior internationally, over time, and inexpensively, in ways relatively uncompromised by sampling issues.

Introduction

Evolutionary psychology posits that behaviors result from complex, evolved adaptations, many of which are universal to a species (Tooby and

Cosmides 2005). As such, it must contend with hypotheses across all levels of human society, from the individual to the species. Testing theories in such a way that can confirm the influence of adaptations across populations is by no means a simple task however. While the majority of studies are carefully designed and implemented upon subsets of a population, there are many rich secondary data sources that can be used to test complex evolutionary theories on a much larger strata of the population, as well as on national and international levels. Such sources are thus promising avenues to confirm or advance contemporary theory. In this chapter, the use of census data is critically discussed, and its use in contemporary literature is illustrated with some pertinent examples.

What Is Census Data and Why Is It Advantageous to Evolutionary Psychology?

Most national governments implement some form of national census every decade. While these are designed for assisting with state functions such as taxation, they nevertheless can be used fruitfully by researchers in the field. These massive data collections are often based on in-depth surveys that catalog the basic demographic characteristics of every household within a nation, detailing everything from the number and sex of household occupants, age, number of children, employment status, and size of dwelling are among just a few of the potential fields available. This provides a snapshot of the population at a given moment in history. While the majority of the basic demographic sections of the survey remain static over time, many governments also include other measures to help supplement future public policy which can also be of use to researchers. In recent years, two societal changes have enhanced the use of such data: public disclosure of census records and online availability (normally with tools to allow users to drill down to multiple levels of municipal administration). The ease of access to such data sets makes them an attractive option for use in research.

Census data has been in use for many years in many other disciplines (particularly sociology and criminology). Generally, however, it is used less in psychology, as its focus is predominantly (but by no means exclusively) on individual level behaviors and cognitions. Evolutionary psychology of course does not ignore these factors, quite the opposite in fact. Where evolutionary psychology differs, however, is in its underlying principles based on the evolutionary science of adaptations (Tooby and Cosmides 2005). One of the core criteria of demonstrating that a behavior or cognition is an adaptation is showing that it has consequences for fitness (the ability to leave descendants). This is where census level data is incredibly useful, as it can provide a wealth of accurate, objective information on actual offspring within families and many of the factors surrounding birth and mortality rates. While this may seem limited to a traditional human behavioral ecological approach to research (often referred to critically as “counting babies” – Nettle et al. 2013) the ability to examine population-level (and levels below where it allows) reproductive output provides a crucial window into human behavior.

The second core advantage to evolutionary psychologists is the ability to use this information to carefully compare across populations internationally. An additional criteria for showing evolved adaptations includes the principle of species level universality: if it is an evolutionarily ancient trait, everyone across cultures, nations, and geography should show evidence of it. Demonstrating invariance (or its absence) provides us with powerful information regarding the origin of a behavioral or cognitive trait. As mentioned earlier, most nations conduct a form of census that allows such a comparison to be made and on such numbers to allow us a greater confidence in conclusions emerging from such data. While the impetus to establish invariance, or lack thereof, in a given trait is of course not limited to evolutionary psychology per se (as all disciplines ideally consider cross-cultural variation to be important), its theoretical significance in the study of behavioral origins makes the quest for invariance of greater importance (and is alas examined all too infrequently).

The Methodological Advantages and Disadvantages of Census Data

Two of the core advantages to the use of census data have already been discussed, in that they allow us to tackle core evolutionary questions with powerful, large-scale, national, and international data sets. There are of course added advantages. First of all, many of these data sets are freely available to researchers and can be interrogated meaningfully with relative ease. Secondly, most countries conducting a national census do so on a repetitive timetable (every decade in the UK, e.g.). This opens up opportunities to meaningfully examine stability over time within (and potentially between) nations or other geographical demarcations. While not necessarily a longitudinal study by design, the insights this approach can provide are nonetheless important (Copping and Campbell 2015). Thirdly, the data sources are often rich enough with demographic information to allow us to transform and compute other evolutionarily significant variables of interest (actual and operational sex ratios, for instance). Variables such as these that are hard to consider without an actual figure or, at the very least, an accurate estimate of local male and female populations (stratified by age) are often difficult to obtain by other means. However, the ability to calculate such variables on a population level allows us to expand the range of evolutionary questions that can be considered. Fourthly, data that allows researchers to drill down into smaller geographical units can be used to act as indicators of the local environment that can be used as measure (if only a proxy measure) of local circumstances for the purposes of modelling. This again can be informative for the purposes of testing theory, in particular, mid- or higher-level theories (such as life history theory). Finally, the use of such data allows us to partially mitigate the atomistic fallacy (where correlations on the individual level may not reflect the same relationships at higher-order group levels – Robinson 1950), something that can be hard to avoid when making conclusions and generalizations from smaller sample sizes.

There are of course limitations that one must be aware of when using such data; no method is after

all perfect. While these data are valuable for study, they can be limiting in terms of the questions that we can answer from them. Unlike a study designed to test a specific theory or research question, census data is limited to the pool of items it has collected (or that which can be meaningfully expanded from it). This often means that researchers may have to rely on variables that do not fully examine the construct of interest or that proxies have to be used instead. Despite the power of the sample, this often means we cannot always be as confident in the findings as we would like (Copping and Campbell 2015). Comparisons over time and nations also posit some difficulties if the nature of the surveys change over time and place, as national agendas change frequently with different governments. Related to this is the challenge of readily combining data sets (from other public records, e.g.) within nations so that they provide a meaningful snapshot of the conditions of interest. This can be frustrating when some fields of interest may not have been collected at the same time, forcing researchers to make additional assumptions about their data. Finally, just as examining individuals leaves us open to the prospect of the atomistic fallacy, examining higher-order levels of data can lead us to make the ecological fallacy (Robinson 1950). Just because we see something happening at the level of various social stratifications doesn't mean the same effects are necessarily generalizable to the level of the individual. Related to this is also the danger of Simpson's paradox (Simpson 1951), where meaningful differences in populations can be masked if data is aggregated on higher levels. These problems of causal inferencing however are not limited to the use of census data, and responsible researchers need to be careful in how they interpret the data so as to not make inaccurate or misleading conclusions.

How Has Census Data Been Used to Advance the Evolutionary Sciences?

There are many pertinent examples of how census data has been used over the past decades to help

answer important, evolutionarily derived questions. While these studies have some of the methodological shortcomings mentioned earlier, they are important attempts to exploit these valuable sources of data nonetheless.

One area of evolutionary psychology has benefited in particular: life history theory. Life history theory is a mid-level evolutionary theory that examines differential resource allocation across different environments and how potential trade-offs between investments can result in differential expression of various behaviors (such as aggression, early maturation, sexual precocity, etc.). Accounting for the wider environment, however, which is of course a critical stress-causing feature of daily life, is difficult to do objectively. Census data and public records however help us enormously to paint a picture of the ecological niches that modern man inhabits. An early example of how this can be achieved comes from Wilson and Daly (1997) who examined the impact of life expectancy and economic deprivation on homicide and early birthing rates. Using a combination of public health data and census data, they were able to compare 77 districts in the US city of Chicago, demonstrating that more affluent neighborhoods had higher life expectancies, which in turn had lower homicide and age-specific birth rates.

More recent work has taken these findings further. Copping et al. (2013) conducted a similar analysis using the UK census data (2001) and public records to analyze rates of criminality and teenage pregnancy across local authorities in England. They expanded the analysis to include more data that could encapsulate the environment in more detail and created a series of structural models to evaluate theories surrounding how the environment impacts upon behavior from a life history perspective. This study broadly confirmed the analysis of Daly and Wilson and also posited a model of the factors that may have differing levels of impact in increasing violence and sexual precocity. While this large-scale analysis was interesting, its findings were limited by the ecological fallacy. In an attempt to mitigate this, Copping and Campbell (2015) followed up this work by comparing the

same data from the 2001 census with the 2011 census. They found firstly that the original model was stable over the two capture points. Furthermore, they conducted a study using questionnaire data on the general public to capture similar variables to those recorded in the census. They also used postcode data from each participant to link the behavior of the individual to the local information captured in public records (in order to capture some of the wider ecological factors around each participant's home neighborhood). The findings of this study seemed to highlight a model that was very similar to the structural model created using census data only. While the two models were imperfect representations of each other, the obvious similarities between the two reinforced the conclusions of the original study and demonstrated how sources of data can be combined within research designs in novel ways to negate the ecological and atomistic fallacies.

Briefly alluded to earlier was the use of census data to calculate demographic characteristics such as sex ratios. Several theories suggest a key role for the impact of differing proportions of reproductively viable males and females, and census data provides an excellent opportunity to examine this in depth. For instance, previous research has suggested that a paucity of males can lead to elevated levels of localized violence, single-parent families, precocious sexual activity, and many other social phenomena. At the same time, a paucity of females has suggested much the same pattern. Combinations of census and public record data however seem to suggest that fewer males relative to females in the reproductive population (the operational sex ratio) is a key driver of aggression (Barber 2003; Messner and Sampson 1991) due to the instability it creates due to the lack of parental investment in offspring (as males are able to move more freely between sexual partners without having to make longer-term investments). This effect has been shown repeatedly across time periods and nations. This finding would have been difficult without readily available census data sets that accurately recorded population compositions at each point.

Future Directions and Conclusions

Evolutionary researchers need to begin exploiting these rich data sources more frequently to assist in answering pertinent research questions and to allow greater historical and cross-cultural trends to be examined. Such studies can greatly assist in answering questions regarding the universality of various behaviors. Furthermore, the use of this data can also paint pictures of various environmental settings. Cataloging local environments is a difficult task at the individual level and includes many different levels of objective and subjective perception (Nicotera 2007). Census data can at least provide some guidance on various environmental facets worthy of greater exploration. Furthermore, fruitfully combining public records with individually gathered data may also help establish the validity of many evolutionary theories while avoiding the pitfalls of the atomistic and ecological fallacies (Copping and Campbell 2015). While pertinent examples have been discussed here regarding the previous use of census data, much more can still be achieved if study designs incorporate this important source of information.

Cephalopod Tool Use

Jennifer Mather
University of Lethbridge, Lethbridge, AB,
Canada

Synonyms

Item manipulation

Definition

The tool must not be part of an animal itself, must be not attached to the environment, and must be manipulated by the animal to achieve some beneficial outcome (Beck 1980).

Introduction

Beck's (1980) definition of tool use can be applied to the cephalopod mollusks. It has been found in

two of the three major classes, the octopuses and cuttlefish, though not so far in the squid. Even with the limited examples that we have, tool use by this group touches on the major questions and controversies in the area. This account will evaluate the ecological and phylogenetic constraints on cephalopod tool use, where actions fit at the boundaries of the category as defined and the extent to which their use of tools is linked to cephalopods' cognitive capacity.

Why Tool Use?

Why would cephalopods use tools, given their tremendous manipulative capacity and flexibility? With their boneless muscular hydrostat movement system (Mather and Alupay 2016), eight flexible arms, and two extensible tentacles in cuttlefish and squid, the cephalopods have a tremendous ability to manipulate and move items. Their arms are lined with suckers for adhesion, and squid tentacles often have hooks to assure that fish prey is firmly held when captured. Octopuses have hundreds of suckers, and they can be folded together to make a pincer grasp that allows the animals to even untie knots in surgical silk. For instance, faced with a tightly closed bivalve shell, an octopus can perform actions that other species might use tools to assist them with. They pull the valves apart with the strong arms, drill a hole with the salivary papilla or chip the edge with a parrotlike beak, and inject a poison to weaken the adductor muscles (Anderson and Mather 2007). After pulling the valves apart, they remove flesh with a radular ribbon of teeth, having no need for tools through this sequence of actions.

One of the reasons that cephalopods might use tools even though they have such an ability to manipulate items is the medium in which they live. Mann and Patterson (2013) point out that the aquatic medium constrains and channels the use of tools by marine animals. While the oceans are immense three-dimensional ecosystems, items available as tools are likely only found on the sea bottom, in the benthic habitat. This probably accounts for the fact that squid, which generally are not near the sea bottom, have not been found

to use tools. However, there is a clear observational bias based on where researchers have been able to look. We know little about the normal behavior of a group of animals that often live hundreds of meters below the water surface and thousands of meters out into the ocean. As well, the high density of water means that actions are slowed; you cannot hammer under water. Yet this same density means that water itself can be used as a tool, and octopuses and cuttlefish, as well as fish, do so. And since sand or mud makes up much of the ocean floor, perhaps water is the best tool to move these small particles around.

Water as a Tool

Much of the known cephalopod manipulation uses water as a tool, and this is linked to the animals' anatomy. One of the basic characteristics of mollusks is the presence of a mantle cavity, somewhat analogous to mammalian lungs. Most mollusks use the mantle to secrete a rigid protective shell and then use the water-filled cavity within it for respiration, sometimes also for feeding. Coleoid cephalopods (all but nautilus) have lost the shell so the mantle expands and contracts, and in addition they have evolved a flexible funnel for exhalation. Water output can therefore be directed, and the water circulation is modified for uses other than respiration. The exhalation jet is commonly used for locomotion (Alexander 2003), especially for escape in squid, but also for other actions on the environment. Such use allows us to evaluate the specificity of Beck's (1980) definition, as well as the cognitive capacity used in tool manipulation. How does water use fit his definition?

Sepioids (cuttlefish and allies) are blimp-shaped animals that shelter in the sand or mud during the daytime. They bury by sending jets of water underneath their body and displacing the substrate and then placing more of it on top of their body. von Boletzky and von Boletzky (1970) first evaluated the actions of several species from this group and suggested that the digging procedures were a species-specific fixed action pattern. This is partly true. For instance, the cuttlefish

Sepia officinalis settles onto a sand bottom, blows jets of water out under its body, usually in a forward-back-forward-back-back patterns, and then sends a sideways shiver through its dorsal mantle to disperse the sand that has landed on it (Mather 1986). *Rossia pacifica*, a small dumpling squid, blows jets of water forward and back, pauses and then extends a pair of arms forward and laterally, cups some substrate in the distal part, and throws it back over the head and body (Anderson et al. 2004). The arm retraction sequence is fixed, continued even when the cupped arm doesn't manage to capture any sand. The similar *Euprymna scolopes* jets backward first, alternates jet directions, and then similarly sweeps sand or mud over its dorsal surface (Anderson et al. 2002).

Such use of water can be investigated for its link to cognition. Although tool use is not automatically associated with cognitive complexity, it is commonly expected to be (St Amant and Horton 2008; Hansell and Ruxton 2008). Cephalopods are known for their behavioral flexibility (Mather 1995); are these digging sequences, as Mather (1986) first thought, an exception? In fact, although sand digging has a clear sequence of acts, the sequence is internally flexible. The unit size of marine substrates varies, from tiny mud particles to visibly separate gravel pieces. Placed on gravel that cannot be dug into, *Sepia* uses its skin pattern camouflage (Hanlon and Messenger 1988) to resemble the background. If it is put on a gravel substrate, *Rossia* attempts to dig by blowing water jets, and when that does not succeed, it reaches under the body and curls the arm tips around gravel grains, pulling them out from under and throwing them forward until the animal rests in a depression and there are two gravel piles at about 45° from its anterior (Anderson et al. 2004). Then it picks up individual grains and places them on top of its dorsal surface. This behavioral flexibility allows the animal to use different actions to accomplish the same purpose, but by Beck's (1980) definition, the action had changed category from tool use (using water) to not tool use (using the arms). This also clearly illustrates how arbitrary the boundaries of defined tool use is. Hansell and Ruxton (2008) point out

that Beck (1980) was aware of how arbitrary these boundaries could be, and they argue for a clearer understanding of the continuum between tool use and similar non-tool construction behavior, especially nest making.

A similar flexibility is embedded in the sequence of actions in *Sepia* burying, as both duration of digging and number of blowing actions were affected by substrate type (Mather 1986). When sand depth was too shallow for full coverage, animals dug for longer, and transition between acts in the internal sequence of water jets was more predictable for medium and fine sand than for gravel and too-shallow sand. Clearly jet-assisted digging is a species-typical spatiotemporal pattern of movements (sensu Barlow 1968), yet it is also affected by feedback cues. *Rossia* pauses for over a minute after blowing water jets, presumably for assessment, before moving to the subsequent action of throwing sand over the dorsal surface (Anderson et al. 2004).

The better-known octopus has considerable tool use. The mantle-funnel complex is a fundamental structural unit of the octopus body (Mather and Alupay 2016) and moves water for many purposes, only some of which would qualify water as a tool. Water enters and passes along the gills for respiration. The anus and renal papilla are near the base of the funnel, so feces and urine are expelled out of it; similarly, the male “penis” passes spermatophore sperm packages to the groove in the specialized third right arm, which conveys them to the female. Ink from the ink sac passes out the funnel and is used as a visual barrier against potential predators and also a chemotactile repellent of fish (Wood et al. 2010). Since ink is an internal product, this is not tool use, even though ink is manipulated externally. But when jets of water are used to repel scavenging fish (Mather 1992), water jets join the category of tools. Fish are not the only target, as such jets may be aimed at conspecifics and even researchers attempting to evaluate home characteristics and midden heaps (Mather 1994). They may even be aimed at those in the air outside a laboratory tank that “annoy” the octopus (see Dews 1959, for a published example, but this is well known among octopus researchers). Similar water jets are used by archer

fish to knock insect prey off low-hanging branches (Schuster et al. 2004).

Octopus Tool Use for Shelter Formation

A soft-bodied animal without camouflage or repellent properties must find shelter to rest. Octopuses have a wide variety of actions to find and modify such shelter, some of which qualify as tool use. Given a choice, an octopus has clear specifications of characteristics for a shelter – somewhat larger volume than its own, small entry area, and only one entrance (Mather 1982). But in the natural environment, there are few such “perfect” homes. Thus, *Octopus vulgaris* enters a less-than-perfect space and modifies it with several actions, some of which are tool use. The octopus pushes out gravel and small rocks – not tool use. It blows out sand with water jets – tool use – and pulls off dangling algae fronds – again not tool use. Faced with an entrance that is larger than the area needed for its malleable body to pass through, an octopus brings small rocks to block the entrance, sometimes described as a wall, with a significant correlation between the area of entry and the number of small rocks gathered and placed in front of it (Mather 1994). This is also tool use, though see the problem that nest construction (Hansell and Ruxton 2008) may not be included in the category because of the “action on” specification. The variety of behaviors for the same purpose that differ in their inclusion in the tool use category reinforces the authors’ assertion that such behaviors are on a continuum of manipulation.

One clear example of octopus tool use to manipulate shelter is Finn et al.’s (2009) observation of coconut-carrying octopuses. *Amphioctopus marginatus* moving out across soft-sediment substrates often carried two halves of a discarded coconut shell with them. At some point, the octopus stops, rotates the halves of the shell back to their original orientation, and pulls them together to use as a shelter. Not only is this tool use, it suggests the foresight that must be true for all shelter “construction” (Hansell and Ruxton 2008). When the coconut shell was collected, it was not presently useful,

and it was only minutes or hours later that the octopuses choose to manipulate and reassemble into the appropriate structure. It also shows that cephalopods combine intelligence and manipulative capacity in ways that researchers can use to explore and perhaps reevaluate the boundaries of any tool use definition.

Conclusion

Tool use is present in at least two of the major classes of cephalopods, but the observed actions are the result of scattered and opportunistic evaluation of the capacity of these marine animals in the field. Given their manipulative capacity and behavioral flexibility, we can expect that many more examples will be found in cephalopods as our opportunities expand, and they will help broaden our understanding of the animal use of tools.

Cerebellum, The

Christoforos Christoforou
University of Nicosia, Nicosia, Cyprus

Synonyms

Cerebrum; Littlebrain; Parencephalis

Definition

The cerebellum constitutes a principal anatomical structure of the brain that is in the back part of the brainstem. The cerebellum is accountable for various operations related to the regulation of the functional qualities of motor activities including motor-coordination, motor-balance, and body posture.

Introduction

Cerebellum constitutes a principal structural section of the metencephalon that accommodates numerous ascended as well as descended major passages and a section of the reticular configuration. The cerebellum represents a big, intricate structural section of the brain stems dorsal surface and it is a significant sensorimotor structure. In human beings, the cerebellum exerts very significant operational functions related to motor control and it is also associated with various cognitional operations including attention and language and the regulation of fearful and pleasurable reactions. Yet, its functional qualities related motor control and dynamics are the most firmly recognized and generally accepted. Moreover, the cerebellum in humans is involved mostly in motor-coordination, motor-precision, and exact-timing and does not initiate movement. Furthermore, cerebellum receives information from sensorial structures of the spinal cord as well as from other structural sections of the brain and joins in this information to precisely regulate motor activities. For instance,

it has been consistently cited that impairment of the cerebellum significantly reduces the capacity to accurately coordinate motor activities and to adjust them to varying environmental circumstances.

The operational intricacy of the cerebellum is indicated by its structural design (Pinel and Barnes 2017). For instance, even though it represents just the 10% of the brain's mass, it houses more than half of the brain's neurons (Passingham and Wise 2014). Additionally, the cerebellum obtains inputs through the primary and secondary motor-cortex, inputs related to the descended motor-signals by the brain-stem motor centers, and information through the motor-activities by the somatosensory and vestibular structural mechanisms (Glickstein and Doron 2008). The cerebellum is considered to evaluate these three structural centers of information so that to coordinate constant motor-activities which had deviated from their planned reaction (Wickens 2011). Through the performance of this sequential operation, it is considered to exert a principal role in the functional process of motor-learning, mainly in the learning of the order of motor-activities in which precise coordination is a vital component in the execution of a favorable outcome (Pinel and Barnes 2017).

The consequential outcome of a diffused impairment on the cerebellum when it comes to the execution of functional and well-coordinated motor-activities is significantly overwhelming (Houk and Wise 1995). Specifically, people who experience cerebellum damage lose the capacity to coordinate in a precise way the course, strength, speed, and range of motor-activities as well as the capacity to adjust fixed designs of motor-output to varying circumstances (Mariën and Beaton 2014). Additionally, it is significantly hard to preserve stable stances, and efforts to do so often result in tremor (Allen and Courchesne 1998). There are also severe impairments in motor-equilibrium such as the way an individual move, talks, and coordinates eye-movement. Furthermore, following cerebellum damage, learning of new patterns of motor-activity is extremely hard (Pinel and Barnes 2017).

Conclusion

The last few decades, research findings based on functional brain images related to the activity in the cerebellum of clinical and nonclinical populations have consistently indicated that the functional qualities of cerebellum involve both the learning and adjustments of cognitional reactions and learning and adjustments of motor-activities in the continually changing environmental conditions so that to achieve the desired performance that facilitates adaption within a person's environment (Pinel and Barnes 2017).

Change in Male Hunting Returns

Raymond Hames
Department of Anthropology, University of
Nebraska-Lincoln, Lincoln, NE, USA

Synonyms

Production

Definition

Variation in the amount of game produced or efficiency in hunting by men.

Introduction

Research on changes in male hunting among hunter-gatherers addresses two important issues in early human evolution: the nature of the family and trade-offs in mating and parenting effort as well as the development of embodied capital. In the hunter-gatherer literature, there is a debate about the function of male hunting that has implications for understanding the role males play in the evolution of the pair bond. The traditional model argues that male hunting and other economic activities are forms of male provisioning or parenting effort designed to enhance a man's fitness through his wife's reproduction and the survivorship of their common children. Thus, it is a component of the traditional division of labor and a foundation for marriage and family. The costly signaling hypothesis (or, "show off") is an alternative to the provisioning model. It is proposed by Hawkes and colleagues who argue that men often seek large and difficult-to-acquire game animals that they widely distribute to camp members. As such, it represents mating effort by demonstrating a hunter's phenotypic quality as a potential mate and/or ally. A number of studies have been published to test the provisioning and signaling hypotheses by examining changes in male hunting returns.

Tests of Variation in Male Hunting Production

The provisioning hypothesis is relatively easy to test, but this is untrue for the costly signaling hypothesis (Hawkes et al. 1997). The provisioning model makes at least three predictions: (1) if a woman's productivity declines as a consequence of her pregnancy or lactation and the associated burden of caretaking an infant, her husband's productivity should increase to compensate for her lowered productivity; (2) the amount of time a man spends hunting or in overall food production should increase with the number of his dependent children; and (3) where males commonly share portions of their hunts, the greatest share of a hunter's catch should go to his own family.

The first prediction of the provisioning hypotheses was tested by Frank Marlowe (2003) on the hunting and gathering Hadza. He showed that men with wives who had nurslings increased their labor effort and food production in response to the lower productivity of their wives. He critically notes that these husbands switched to food resources such as honey which are not widely shared to better provide for their families. Among Ache and Hiwi hunter-gatherers (Hurtado et al. 1992) research shows daily food acquisition of a woman's spouse is negatively related to female foraging effort among the Hiwi, and it is negatively related to foraging time and daily food acquisition among the Ache. Finally, in another Hadza study (Wood and Marlowe 2013, p. 280) male productivity was shown to be associated with marital status such that "On average, single men brought food to camp on 28 % of days, married men without children at home on 31 % of days, and married men with children at home on 42 % of days." Furthermore, the total caloric value of food resources brought back to camp by these three classes of men showed the same statistically significant pattern (Wood and Marlowe 2013, p. 307) of increased production for men with children.

The second hypothesis regarding changes in men's food production was tested a bit indirectly among the Hadza. Marlowe (1999) compared the foraging efforts of men married to women who had their biological children compared to women who had the men's stepchildren. Men with biological children produced more food than men with stepchildren.

The third hypothesis on food sharing has been thoroughly investigated by Wood and Marlowe (2013) for the Hadza. Like many hunter-gatherers and other egalitarian people, food, especially game, is widely shared among coresidents. A prediction of the signaling hypothesis is that males who distribute their resources to other families disadvantage their own families. Such distributions are argued to represent mating effort through costly signaling. Detailed research by Wood and Marlowe (2013, p. 297) show this may not be the case. Their data show that successful hunters retain 42 % of all the game they take,

or 3.8 times the amount that other families receive from their kills. Similar patterns emerged when men shared small game or nongame food such as honey. While it is clear that sharing outside the family leads to increased stature for successful hunters and provides some evidence for the signaling model, alternative explanations for sharing as a form of food security through risk reduction is widely documented among foraging societies and horticultural groups where hunting is important. Finally, this is not to say that productive hunters who share widely are not more martially and reproductively successful: they clearly are (Smith 2004). However, evidence also indicates that the families of good hunters receive social and economic benefits not afforded to poor hunters for the Ache (Hill and Hurtado 1996) and in other societies where male hunting is important.

Crucial tests of the signaling hypothesis have not been forthcoming. Returning to the well-documented association between hunting ability and reproductive success among a sample of foragers (Smith 2004), it is clear that young and unmarried hunters demonstrate their abilities as good hunters by advertising their hunting successes and by sharing widely. There is evidence that such males marry early to young and fecund females. But after marriage, most of the evidence to date indicates that high hunting productivity leads to further investment in wife and offspring, is responsive to family needs, leads to the better treatment of one's family by coresidents, and it is sometimes associated with the acquisition of another wife or extra-pair copulations (Wood and Marlowe 2014).

Finally, there are also age-related changes in male hunting independent of family demand and are based on the long-term development of skills necessary to become a good hunter. For example, "...among Ache foragers of Paraguay, men's strength peaks at around 25 years of age but both meat acquired and hunting return rates (amount acquired per hour spent hunting) peak between 40 and 50 years of age" (Kaplan et al. 2010). Research by Walker et al. (2002, pp. 1–2) on seven hunting and gathering and foraging horticultural societies shows that peak hunting

efficiency is not achieved until the late 30s to early 40s in most groups and remains relatively stable for about 15 years before declining. While rates of return measure skill and potential productivity, actual productivity (daily calories produced) is more important as an effective measure of family provisioning. To this end, research by Hill and Hurtado (2009, p. 3866, Fig. 2) show that total foraging productivity (largely but not exclusively hunting) peaks between the age of 45 and 50 for the hunting and gathering Ache and Hiwi.

Conclusion

Empirical research shows increases in male hunting are most reliably associated with increased familial requirements as the number and needs of dependent children increases and the productivity of a wife decreases as a consequence of pregnancy, lactation, and childcare. Changes in male hunting are most consistently viewed as paternal effort.

Changes in Self-Esteem Motivate Behavioral Changes

Aaron A. Shilling¹ and Christina M. Brown²

Synonyms

Appraisals; construals; Behavioral changes; overt responses; Changes in self-esteem; social pain; Interpretations; Negative affect

Definition

Fluctuations in perceived relational value may be due to ostracism, rejection, or exclusion (Leary and Guadagno 2011). These changes in self-esteem are thought to be followed by cognitive interpretations of the exclusionary situation (e.g., Smart Richman and Leary 2009; Williams 2009). Such appraisals likely influence subsequent behavioral changes, including variations in pro-social or antisocial behavior.

Introduction

Sociometer theory proposes that state, or current, self-esteem changes according to a person's perceived relational value (Leary and Guadagno 2011). Self-esteem thus typically decreases following social exclusion and increases after an episode of inclusion. Furthermore, it is widely believed that appraisals and attributions, or cognitive interpretations, of situations responsible for fluctuations in self-esteem determine subsequent behaviors (e.g., prosocial or antisocial responses; Smart Richman and Leary 2009; Williams 2009). This article reviews the observed link between self-esteem, in its function as a sociometer, and behavior.

Emotional Alarm

The decreased self-esteem posited by sociometer theory is one component of people's emotional response to exclusion, with the others being social pain and general negative affect (Smart Richman and Leary 2009; Williams 2009). However, the neuroscience literature now suggests that there is a common, unifying mechanism that underlies these experiences – the affective component of the pain response, mediated by the dorsal anterior cingulate (Eisenberger et al. 2011). Activation in this region is perhaps best described as an emotional alarm (McDonald and Leary 2005; Shilling and Brown 2016). Much as physical pain is a signal that tissue damage is occurring and that a behavioral change is necessary, social pain and

decreased self-esteem signal that one's inclusionary status is threatened and that behavioral modifications are required.

Cognitive Appraisal

Cognitive appraisals are crucial in determining exactly what that response is, however. At a basic level, neuroscientists propose that consciousness is composed of constantly changing patterns of activated neural modules, and that the activity of these systems is interpreted and spun into a narrative by the language centers of the left hemisphere (e.g., Roser and Gazzaniga 2004). These narrative creations permit individual or situational factors to shape conscious experiences. When it comes to social exclusion, even though the source of one's emotions may be obvious, people can still differ in how they explain or appraise the precipitating event, which has important consequences for their subsequent behavior (Smart Richman and Leary 2009; Williams 2009). At a conscious or nonconscious level, the individual evaluates his or her situation: *Can I connect with others after the ostracism? Can I repair my relationship following a rejection? Is the ostracism controllable?* These appraisals, in turn, determine how the individual responds to the event (Smart Richman and Leary 2009; Williams 2009).

Williams (2009) provides a good deal of evidence suggesting that a lack of perceived control is a major factor in aggressive responses to ostracism, whereas a perceived lack of belonging determines prosocial behavior. Likewise, in their review of the literature, Smart Richman and Leary (2009) emphasize expectations of relational repair as an important predictor of antisocial and prosocial behavior, among many other factors. Williams and Wesselmann (2011) recently synthesized the various appraisals as primarily involving the question of whether or not reconnection is likely in the situation. When the others around a target of social exclusion are seen as strangers, brief acquaintances, rejectors, antagonists, or people who may act in an erratic, unpredictable

fashion, aggression is likely; however, when reconnection is perceived as a possibility, prosocial behavior is likely.

Resource Redistribution

Shilling and Brown (2016) further suggest that it may be instructive to consider appraisals of evolutionarily adaptive needs, such as self-preservation, status, and belonging, as determinants of behavioral tendencies following social exclusion. They propose that appraisals of exclusion determine which goals are prioritized, initiating trade-offs in shared, limited-capacity mental resources in service of the person's most urgent goals. When the appraisal of the situation prioritizes belonging, resources are allocated towards behaviors and processes that aid in social reconnection and away from less-relevant processes. However, when self-preservation or status restoration is prioritized (e.g., when one is interacting with a rejector, Buckley et al. 2004, or when one perceives a decrease in status, Schoel et al. 2014), resources are instead shifted towards more aggressive or self-promoting behaviors in service of protecting the self or regaining one's social standing. Shilling and Brown's idea of resource redistribution thus makes inroads to a more comprehensive understanding of the cognitive and neural mechanisms of responses to exclusion.

Conclusion

When others do not pay a person attention or even explicitly tell that person that he or she is not valued as a relational partner, the person is, quite understandably, hurt. This social pain and decreased self-esteem is adaptive as an emotional alarm, and it is followed by a similarly adaptive appraisal. How the individual construes the episode of exclusion (or rejection or ostracism) results in a reprioritization of goals, followed by subsequent resource redistribution in support of those goals. Indeed, advances in neuroscience and social psychology have

revealed much about the link between self-esteem as a sociometer and specific adaptive behaviors.

Charitable Giving (Peter Singer)

Author; Donations; Morality; Philosopher

Definition

According to Peter Singer, people in affluent societies have a strong moral obligation to donate much, if not most, of their resources to charitable organizations that prevent death and suffering.

Introduction

Most of us believe that morality requires that we give, at best, a modest amount to charity. Giving beyond this requirement may be morally admirable but is not morally obligatory. In an influential early paper (Singer 1972), and numerous subsequent publications (Singer 1999, 2009, 2011), the Australian philosopher Peter Singer has challenged this widespread view. According to Singer, people in affluent societies – including academics reading these lines – have a strong moral obligation to donate much, if not most, of their resources to charitable organizations that prevent death and suffering.

To support his conclusion, Singer appeals to two separate arguments: an argument involving an analogy between particular cases (the argument from analogy) and an argument from general philosophical principles (the basic argument).

The Argument from Analogy

The argument from analogy, sketched in Singer's original paper and developed more recently by Singer and others (Unger 1996), invites us to consider our intuitive responses to the following scenario:

The Pond. As you walk past a shallow pond, you see a child drowning in it. If you wade in, your expensive suit will be ruined. If you don't, the child will die. Should you wade in?

Nearly everyone agrees that you are morally required to wade in. But consider, next, a different scenario:

The Letter. You receive a letter from a charitable organization. The letter asks you to donate an

amount sufficient to prevent a child from dying. This amount is equivalent to the cost of an expensive suit. Should you donate?

Here most people believe that you aren't morally required to donate.

According to the argument from analogy, these different responses are unjustified. If we believe that we should wade in and save the child in the Pond, even at the expense of ruining an expensive suit, we should also believe that we should make the donation and save the child in the Letter, at a comparable cost.

Critics of Singer have resisted the challenge by attempting to identify a relevant disanalogy between the two cases (Ashford 2011). Thus, some critics have pointed out that the child in the Pond is a member of our community, while the child in the Letter case isn't. Morality requires that we assist our compatriots, but it doesn't issue a similar requirement to help foreigners. One could imagine, however, a variant of the Pond in which the child drowning isn't a member of our community, and it seems that most people would still judge that morality requires that you rescue her.

Other critics have pointed out that only you can save the child in the Pond, whereas many others could in principle save the child in the Letter. But again, the details of the Pond may be slightly altered, to yield a variant where there are other individuals in a position to wade in. Supposing that these bystanders decide not to intervene, most people would agree that, just like in the original case, you are morally required to save the child.

Finally, critics have pointed out that, unlike the Pond, where we know that the child will be saved if we take action, the Letter involves considerable uncertainty surrounding the effects of our actions. It seems reasonable to be skeptical, given the lack of relevant information about the charity and the complex causal chain involved. Still, here, too, one can tweak the details and stipulate that the charity has an impeccable track record of effectiveness so that we can realistically expect our donation to have its intended effect. (As will be seen in the next section, such a stipulation is not unrealistic.) Yet even after these adjustments, most people persist in thinking that you are morally required to donate in one case but not in the other.

More generally, for any alleged disanalogy claimed to justify our different moral attitudes toward the two cases, Singer's strategy is to alter the details of one of the cases in such a way that this new pair of cases (1) no longer exhibits the disanalogy and yet (2) continues to elicit the same moral attitudes as the original pair.

The Basic Argument

Singer's basic argument consists of three premises:

First premise: We are morally required to prevent something very bad from happening if we can do so without thereby sacrificing anything of comparable moral importance.

Second premise: Death and suffering are very bad.

Third premise: We can prevent death and suffering without sacrificing anything of comparable moral importance.

From these three premises, Singer draws the conclusion that we are morally required to give much, if not most, of our money to charitable organizations that prevent death and suffering.

The second premise is uncontroversial, at least with respect to pain: even philosophers, who disagree with each other on just about everything, agree that (unwanted, undeserved) pain is intrinsically bad. The third premise may have been somewhat controversial back when Singer first presented his argument. At the time, it was hard to know what an individual could accomplish by donating a given amount of money to a charitable organization. This is no longer the case, however. GiveWell, a highly respected charity evaluator, estimates that a donation of about \$3000 to the Against Malaria Foundation will, in expectation, prevent a child from dying of malaria (GiveWell 2015). For people in affluent societies, giving \$3000 doesn't involve a sacrifice of comparable moral importance to saving a child's life.

Consider, finally, the first premise. It, too, seems relatively uncontroversial. It only requires us to prevent what is bad rather than to promote what is good, and subjects this requirement to the

proviso that the agent shouldn't be asked to sacrifice something of comparable moral importance. Furthermore, the premise could be significantly weakened, to require us to prevent something *very* bad from happening if we can do so without thereby sacrificing *anything* morally significant (Singer 1972, p. 231). Such a weakened principle would be even less controversial but would still issue very demanding requirements.

When considered in isolation, each of the premises thus appears plausible. Yet they jointly imply a conclusion that contradicts what most of us believe. In fact, Singer thinks that this conclusion is so radical that "the whole way we look at moral issues [...] needs to be altered, and with it, the way of life that has come to be taken for granted in our society" (Singer 1972, p. 230).

In response, some philosophers have argued that morality cannot demand so much from us and that therefore Singer's conclusion must be mistaken. As David Lewis remarked in discussing a variant of Singer's original argument, "even if we cannot diagnose the flaw, it is more credible that the argument has a flaw we cannot diagnose than that its most extreme conclusion is true" (Lewis 2000, p. 155). This response, however, assumes that we are justified in believing that morality is not as demanding as Singer's conclusion implies. Other philosophers have disputed this assumption (Sobel 2007).

Explaining Our Responses

As we have seen, Singer argues that our different responses to the Pond and the Letter are unjustified. A separate question concerns the explanation of these responses, to which we now turn.

Considerable progress has been made in the study of moral judgment and decision-making in recent years (Bartels et al. 2015). Perhaps the most influential account in the literature is Joshua Greene's dual-process theory of moral judgment (Greene 2014a). On this theory, the same contrast between implicit unconscious processes (System 1) and explicit conscious processes (System 2) that explains our thinking in most domains (Kahneman 2011) also explains our moral

thinking. Situations involving “up-close-and-personal” interaction, of the sort our ancestors in the environment of evolutionary adaptedness would have encountered on a regular basis, trigger rapid, unconscious responses. By contrast, situations involving distant, impersonal interaction trigger slow, conscious responses. Greene’s dual-process theory could thus explain people’s responses to the Pond and the Letter as resulting from the operation of these two cognitive subsystems.

This scientific explanation may have philosophical implications. So-called debunking explanations seek to undermine the justification of a belief by tracing back its causal origins to an unreliable process of belief formation (Kahane 2011). As Greene notes, “science may teach us that some of our judgments are sensitive to features that, upon reflection, do not seem to matter morally” (Greene 2016, p. 176). As an example, consider incest. Once we understand our negative responses to the thought of sexual intercourse between close family members as originating in selective pressures to avoid birth defects, we may cease to believe that incest is inherently morally wrong.

We may similarly be inclined to distrust our belief that there is a fundamental moral difference between the Pond and the Letter. If Greene’s account is correct, these two situations trigger different responses as a result of a historical accident. We feel that there is a strong moral obligation to save the child in one scenario, but not in the other, because in the environment of evolutionary adaptedness it was possible to help others in personal ways, like wading into ponds, but not in impersonal ways, like donating money. Singer himself favors this sort of debunking explanation. He writes: “What is the moral salience of the fact that I have killed [or saved] someone in a way that was possible a million years ago, rather than in a way that became possible only two hundred years ago? I would answer: none” (Singer 2005, p. 348).

One response to this argument is to challenge the scientific premise on which it rests. Although Greene’s dual-process theory is supported by an impressive body of evidence (Greene 2014b, pp. 700–708), it has attracted some criticism (Nagel and Waldmann 2013). Another response is to question the conclusion drawn from that

premise: even if one grants that this account is correct, and agrees that people’s moral responses are sensitive to irrelevant factors, it doesn’t follow that the conflict between these responses should be resolved in a way that favors Singer’s argument. Instead of concluding that we should save the child in both cases, one could conclude that we should save the child in neither case. To adjudicate between these two possibilities, a more sophisticated debunking argument would be required.

Conclusion

Singer’s arguments for the conclusion that people in affluent societies – including academics reading these lines – have a strong moral obligation to donate much, if not most, of their resources to charitable organizations that prevent death and suffering pose a serious challenge to some of our deeply held moral convictions. Recent developments in the neuroscience and evolutionary psychology of morality have further increased the theoretical appeal of those arguments, both to psychologists interested in explaining our moral beliefs and to philosophers interested in vindicating or undermining their justification.

Charity

Philip J. Grossman¹ and Andrew Luccasen²

¹Monash University, Melbourne, Australia

²Mississippi University for Women, Columbus, Mississippi, USA

Synonyms

Aid; Alms; Contributions; Donations; Gifts; Offerings

Definition (Merriam-Webster)

Generosity and helpfulness especially toward the needy or suffering; aid given to those in need; an institution engaged in relief of the poor; public provision for the relief of the needy.

Introduction

Much research examines why individuals might give to charity. The outputs that charitable organizations create are generally considered public goods; that is, the benefits accrue to society as a whole. A potential donor values the output generated by charitable organizations, but this individual would have the greatest material benefit if others funded the charity. As such, the potential donor has an incentive to not contribute to a charity she values (i.e., the donor has an incentive to free-ride). Samuelson (1954) demonstrates because of this incentive, decentralized markets do not efficiently produce public goods. The strongest version of this hypothesis states that the vast majority of people will not contribute, leaving only the wealthiest individuals to provide all of the funding. Because this implication is easily falsifiable (Andreoni 1988), much research has been devoted to understanding the motivations for charitable giving as well as factors, such as choice architecture, that may affect the amount and likelihood of giving to charity.

Motives for Giving to Charity

Two major motivations for contributing to charity have been identified. The first is a concern for the output of charitable organizations. This motivation is referred to as “pure altruism.” A pure altruist cares only for the total amount of the public good, not how it is funded. An altruistic donor would have the greatest material benefit by free riding and letting others fully fund charity. (Inequality aversion (Fehr and Schmidt 1999; Bolton and Ockenfels 2000) is often identified as a separate motivation. Concern for those with a lower income can be a type of pure altruism, so we do not discuss inequality aversion in detail here.

Furthermore, much empirical evidence for inequality aversion is based on behavior in ultimatum games, dictator allocation tasks, and market competition games. These games match participants with other participants (Chowdhury and Jeon 2014 for example) as opposed to charities (Eckel and Grossman 1996 as discussed below.) The second motivation is the psychic benefit the donor experiences resulting from giving to charity, as opposed to personally benefiting from the production of a charity. This motivation is commonly referred to as “warm glow” or pure egoism (Andreoni 1989, 1990). Concerned only for the private psychic benefits he receives from his gift, a warm glow giver is, therefore, less inclined to free ride on the giving of others. Pure altruism and warm glow are not mutually exclusive motivations. A combination of a concern for the recipient and joy of giving is referred to as “impure altruism.”

Ribar and Wilhelm (2002) suggest that the free riding problem may be a function of the size of donor groups. That is, free riding by pure altruists may be incomplete in small groups of donors but becomes more severe and possibly complete as the number of donors grows. Observed charitable giving in small groups may be motivated by impure altruism; in very large groups it may be motivated solely by warm glow.

Evidence for Motives

List and Samak (2013) study the charitable motivations of children between three and five years old. Children were given five marshmallows and were paired in a dictator allocation task with either another child or a teddy bear. The children were told that teddy bears do not like marshmallows, but do enjoy eating cotton balls. In some treatments, marshmallows passed to the recipient were placed in a “magic box” that could turn marshmallows into cotton balls regardless of the recipient being a child or teddy bear. The design allows the researchers to determine if young children give to improve the well-being of the recipient (pure altruism) or give for the sake of giving (warm glow). Children are shown to be altruistic, as average giving is 25% of the endowment. Yet,

children rarely give marshmallows to teddy bears or cotton balls to other children, which suggests that the primary motive for giving at this age is pure altruism. The authors argue that preferences for warm glow are acquired later in life.

Because experimental studies typically involve giving to an established charity or other individuals (occasionally, but not always individuals in need), it is difficult to separate pure altruism from warm glow. Any amount passed to increase the well-being of others could create a warm glow effect. The warm glow motivation is isolated in experiments by Crumpler and Grossman (2008), Luccasen and Grossman (2017), and Gangadharan et al. (2017). In these experiments, a charity (or individual served by a charity) receives an endowment from the experimenter. A participant can pass from her own endowment to a charity, but any amount passed is known to reduce the experimenter’s contribution by an equal amount. Participants cannot therefore increase the amount received by the charity, but giving to charity in this context could create an impression that part of the charity’s fixed donation came from the participant. In these studies, approximately 40–60% of participants pass money to charity, giving 15–20% of their individual endowments.

Preferences for giving to charity are likely to depend on the characteristics of the charity. Vesterlund (2015) describes motives for giving to charity as analogous to demand functions. An understanding of the demand for one good does not generalize to the demand for all goods. Pure altruism may be the primary motivation for a donor to give to public radio, but warm glow may motivate the same individual to give to charity in the immediate aftermath of a natural disaster.

Ottoni-Wilhelm et al. (2014) identify motives by examining the responsiveness of individual donations to charity to changes in the donations of others, operationalized in their experiment by exogenously changing the amount donated by a foundation. Participants were given the opportunity to donate to an individual child who was not harmed but lost his or her house in a fire. Participants were told a foundation would also contribute to the same specific child the participant was

matched with, and the foundation contribution ranged from \$4USD to \$34. The sensitivity of donations to the foundation's contribution depends on the level of the foundation's contribution. The authors report 44% of participants are motivated by pure altruism, 39% by impure altruism, and 9% by warm glow.

Gangadharan et al. (2017) take a different approach to identifying motives for giving. Their design is a sequence of donation tasks that allows them to observe the subjects' warm glow and/or altruism motivations for giving. In their first (Warm Glow) task, participants donate to their specific recipient, the recipients were served by a private charitable organization, in an environment where the donations are fully crowded out. In the second (Altruism) task, subjects are given a second opportunity to donate (to the same recipient), but with all donations going to the recipient. The authors report that 26% of participants are motivated by pure altruism, 31% by impure altruism, and 15% by warm glow. A further 28% were non-givers.

Social norms or a concern for image may be another motivating factor to contribute to charity. Social norms influence the decision to give to charity and the amount to give to charity. One common social norm is to tithe, which is contributing a fixed percentage of one's income to charity. Rather than receiving a warm glow from giving, some donors have an aversion to declining the opportunity to give, and thus respond to social pressure (DellaVigna et al. 2012). Blood donors in an Italian town respond to symbolic prizes, but only if the prizes are publicly announced (Lacetera and Macis 2010). Izuma et al. (2008) employ fMRI brain imaging to show that positive social rewards activate the same "reward circuitry" in the striatum as monetary rewards. (We do not review the literature on charitable giving for explicitly extrinsic motivations or for signaling (for example, making a large donation to a university to influence an admission decision). Although we do discuss the role of social image, which could be considered a type of extrinsic motivation, for more on the signaling motive, see Blumkin and Sadka (2007).)

Factors Affecting Giving to Charity

Because of these different motivations for giving, policies designed to affect giving will vary in their effectiveness. Perhaps the most direct method to affect giving to charity is to alter the financial incentives. Many governments encourage donations to charity by deducting donations from taxable income, which reduces the price of giving (Andreoni 2001). Behavioral sciences have not only expanded the range of policies studied beyond purely financial incentives, but also have provided additional insight into traditional policy tools. For example, should a government choose a rebate subsidy or a financially equivalent matching subsidy? Eckel and Grossman (2003) show that although these policies are financially equivalent, in practice the matching subsidy significantly increases donations to charity. Benabou and Tirole (2006) argue that donors motivated by warm glow prefer the matching policy over a rebate because receiving a rebate emphasizes the personal gain, thereby reducing the joy of giving to others in need.

Individuals learn norms and appropriate behaviors by cultural assimilation. Bowels and Polania-Reyes (2012) identify mechanisms (not mutually exclusive) through which explicit economic incentives affect ethical norms, altruism, or other social preferences for prosocial behavior. While explicit incentives are often designed to encourage prosocial behavior, incentives can have the opposite effect because an incentive can signal (i) an activity is not pleasant or appreciated, (ii) most people do not engage in the activity without the incentive ("moral disengagement"), and/or (iii) the activity involves a loss of agency and self-determination. As an example, a policy of paying blood donors may reduce donations because the explicit incentive interferes with the ethical norm or social-preference signal (see also Mellstrom and Johannesson 2008). An individual may adhere to a social norm of charitable giving for a variety of reasons, ranging from avoiding social sanctions to a genuine concern for the recipient (pure altruism). To the extent that individuals observe norms to signal group identity, such charitable giving is consistent with the warm-glow motivation.

Religious beliefs could plausibly affect giving to charity, and relationships between religion and charity are a focus of academic research. Eckel and Grossman (2004) find no significant difference in the response of religious and nonreligious individuals to changes in subsidies to charitable giving. However, the religious are more sensitive to changes in income than the nonreligious. Controlling for wealth, income, education, and other family characteristics, Ottoni-Wilhelm (2010) finds no differences in giving among Black Protestant, Evangelical Protestant, Mainline Protestant, Catholic, and nonaffiliated families. Further, Jewish households are more likely to give to charity, and give greater amounts than Christian families. Parrett and Grossman (2011) conduct a field experiment to study religion and tipping at restaurants. Although the context is not a charity per se, the results do address prosocial behavior, a major determinant of charitability. The authors do not observe greater prosocial behavior among those with a religious affiliation.

Empathy or an internalized value of caring for others may be a stronger predictor of charitable giving than religious identity (Ottoni-Wilhelm and Bekkers 2010). Andreoni et al. (2017) report a field experiment involving the Salvation Army that provides insight into the link between empathy and charitable giving. The authors noted that their experiment is not a direct test of any theory of empathy but it is consistent with underlying empathy as a prerequisite to charitable giving. In the experiment, Salvation Army bell-ringers are stationed in front of either one or both entrances of a large retail store. With a solicitor stationed at only one of the two entrances, customers could have avoided solicitation. The authors find a significant increase in charitable giving when a solicitor is stationed at both entrances, and giving increases further if the solicitors verbally ask passing individuals to give. Andreoni, Rao, and Trachtman argue that those who avoid solicitation when possible are not uncharitable people, but rather are “passive givers” with a latent desire to give. To use the authors’ example, just as someone who enjoys cake does not eat cake at every meal, charitable donors also attempt to regulate their temptation to give at every opportunity. Empathy

precedes giving to charity, and the impulse to give can be easily triggered.

Giving to charity is also influenced by image concerns, including what others may think (social image) and one’s own self-image. Reporting both laboratory and field data, Ariely et al. (2009) examine the behavior of individuals raising money for charity. The study manipulates both the visibility of the individual’s fundraising and whether the individual receives financial compensation. In treatments without financial compensation, individuals exert more effort in public than in private. Offering financial incentives did not increase public effort, but did increase private effort. These results show that individuals care about how they are perceived by others. Self-image is also an important motivator. Grossman and Luccasen (2017) conduct a laboratory experiment in which participants can give to charity from their own endowment of \$15, or can take money from a charity’s endowment of \$5. Individuals in some treatments make this decision by distributing cash between two envelopes in private, then deposit the charity’s envelope in a drop-box as they exit the room. In this highly anonymous environment, the authors cannot link a participant to an allocation decision, but can infer from the amount in each envelope if an individual gave to charity or not. In treatments in which participants privately allocate cash between envelopes, nearly 40% of individuals donated money to charity. Moreover, the average donation of these participants resulted in the charity receiving more than half of the total money available. Giving to charity in this double-blind setting, in which participants could have easily taken money, suggests that many people act to maintain a self-image of charitability.

Gender differences in giving have received considerable attention. In the dictator game, with the recipient an anonymous other subject, women are often observed to be more generous but the difference is not always significant (see Croson and Gneezy 2009 for a survey of gender differences in dictator games). However, in real donation experiments (Eckel and Grossman 1996), where giving is to a good cause such as a charitable organization, studies more consistently find

that women donate significantly more than men (see, for example, Carpenter et al. 2008; Crumpler and Grossman 2008; Eckel and Grossman 2003; Eckel et al. 2007; Fong 2007; Li et al. 2011; List 2004).

Donors appreciate agency over the use of funds and the timing of donations. Eckel et al. (2005) study the effect of tax-financed donations. The authors find that a tax and transfer policy reduces voluntary giving if the forced donation is made apparent, but an opaque fiscal policy does not reduce giving. Eckel et al. (2017) conduct a field experiment at a public university in which donors have the option to direct their donations to a specific college. Donations are higher with the option to direct giving, although remarkably few donors use the option. Li et al. (2015) report that the opportunity to direct giving more than doubles both the likelihood of giving and the size of contributions. Andreoni and Serra-Garcia (2016) note that many donors exhibit time inconsistency. Some donors will pledge a future donation but often will not donate immediately, while others display the opposite behavior by donating immediately but would not commit to a pledge of future donations. Donors prefer flexibility regarding the timing of donations, and the authors show that a simple thank-you note can reduce renegeing among those who self-select into pledging future donations.

Conclusion

Charities generally pursue goals that benefit society. As an example, a charity that provides assistance to a low-income household so that the head of the household transitions out of poverty clearly creates benefits to the household. Moreover, such an outcome benefits all individuals who care about poverty and income inequality. Because the societal benefits are greater than the private benefits, individuals may attempt to free ride on the donations of others, resulting in an inefficiently low level of activities provided by the charities. Governments and charities wish to understand donor motives, and what policies increase charitable giving. Although models of charitable behavior have

been developed and the efficacy of many policies has been studied, to date little research examines the general equilibrium effects of any policy. A successful campaign by one charity may increase total giving to charitable organizations, or the increased donations from one organization may come at the expense of another.
